CLINICAL AND EXPERIMENTAL

AN EXPERIMENTAL STUDY OF THE LYMPHOCYTIC RESPONSE IN THYROTOXICOSIS*

L. A. TURLEY, PH.D., AND K. M. RICHTER, PH.D.
OKLAHOMA CITY, OKLA.

POSITIVE evidence for the existence of a thyroid-lymphoid relationship is indicated by numerous clinical and pathologic observations (Plummer,¹ Falta,² and others) and by numerous experimental studies (Hoskins³; Kahn⁴; Gudernatsch⁵; Marine, Manley, and Baumann⁶; and Adams and Shevket⁷; and others), but positive evidence showing whether the lymphatic hyperplasia and consequent lymphocytosis is or is not functionally related to the hyperthyrosis is lacking; although, as Rowntree⁸ points out, thymic hyperplasia in exophthalmic goiter has been considered by some as a compensatory hypertrophy, and Gudernatsch concluded that the thymus, spleen, and perhaps other lymphoid tissues as well, constitute glands with a positive internal secretion.

The present study was initiated by the constant observation by one of us (Turley) through thirty years of pathologic investigation that (1) hyperthyrosis is accompanied by a lymphocytosis; (2) the phenomenon of lymphocytic infiltration of the thyroid gland in thyrotoxicosis is interpretable in the light of the law of phagocytic infiltration, viz., that phagocytes infiltrate tissues at the site of pathologic processes; (3) all experimental work so far reported could be interpreted on a functional basis; and (4) the relation, whatever its nature, involved the lymphocytes as cells more than it did lymphatic tissues as organs. In view of these indications it seemed desirable that an attempt be made to determine whether the generalized lymphoid hyperplasia and the lymphocytes in thyrotoxic lymphocytoses are performing a function related to the thyrotoxicosis.

*From the University of Oklahoma School of Medicine, Oklahoma City.

These studies were financed from funds appropriated by the State Legislature for research in the Medical School.

Received for publication, August 19, 1940.

METHODS

The experimental animals used were guinea pigs weighing between 300 and 500 Gm. each. The animals were divided into three groups. In group I each animal was fed a balanced diet to which was added either 1 or 4 grains of thyroid substance daily. In group II each animal was fed daily a normal diet plus 1.5 Gm. of aleuronat. In group III each animal received daily 1 grain of thyroid and 1.5 Gm. of aleuronat plus a normal diet. Four animals were used in group I, 6 in group II, and 8 in group III.

Total and differential blood counts, hemoglobin estimates, and weighings were made daily on each animal. As nearly as possible, blood was taken from each animal at the same hour every day. To avoid a generalized traumatic reaction in the ear and its possible effects on the blood picture, a single ear vein was severed in the right and left ears on alternate days. When deaths occurred, autopsies were done and tissues of all pertinent organs were taken for microscopic study.

In a preliminary series of studies the animals of groups II and III contracted pneumonia during the course of experimentation. This complicated our results and made it difficult, if not impossible, to distinguish between the immediate effects of the drugs administered and the effects of the pneumonic condition. Because of this complication, and because of the positive indications of these experiments, a second series of groups II and III experiments were performed, during which our animals were maintained free of intercurrent infection. In the following discussion of these studies, all remarks concerning groups II and III have reference to these second series unless definitely stated to pertain to the first and preliminary groups II and III experiments.

RESULTS

Group I: The average survival time of these animals was three days. Of this group animals 1 and 2, receiving 1 grain of thyroid daily, lived 3.2 days; and animals 3 and 4, receiving 4 grains daily, lived only two days (Fig. 1A).

All the animals lost weight rapidly. Those receiving 1 grain of thyroid lost 29.5 Gm. daily, and those receiving 4 grains lost 72.5 Gm. daily (Figs. 2, 3A).

Erythrocyte counts varied individually and according to the amount of thyroid substance administered. The number of red blood cells increased in those animals receiving 1 grain of thyroid substance and decreased in those receiving 4 grains (Fig. 2).

Four prominent alterations in the leucocytic formula occurred. (1) In all but one animal a persistent leucopenia developed. (2) In all animals lymphocytes were dominant, both absolutely and relatively, during experimentation. (3) All but one animal showed an absolute but variable increase in the number of lymphocytes at the end of the first experimental day, and on all subsequent days an irregular but absolute decrease in lymphocytes occurred. (4) In every case the number of neutrophils decreased during experimentation (Fig. 2). Significant alterations in the number of eosinophiles, basophiles, and monocytes did not occur.

Group II: No deaths occurred during the course of experimentation which lasted thirty-two days (Fig. 1). Animal 4 was sacrificed for tissue and autopsy on the fifty-first day, and the others on the 120th day. The autopsy material appeared negative.

Except for an occasional variation, all the animals in this group gained weight during the course of experimentation. Animal 2 developed a temporary infection and was disregarded in our interpretations. Animals 1, 3, and 4, considered collectively, gained weight at the rate of 1.3 Gm. daily (Figs. 3A and 5). Weight changes in these animals occurred in diphasic cycles; that is, for a period of one to three days weight increases of 3 to 10 Gm. daily occurred, and then for a period of about the same duration little or no weight would be gained, or a little might be lost. Such diphasic cycles are repeated (Figs. 5, 6).

Fig. 1.—A comparative chart showing the survival time in days of the animals of experimental groups I, II, and III. 4, second series of experiments which were free of intercurrent infection; B, preliminary experiments in which pneumonia intervened; C, animal 3, the only group III animal to die of this treatment.

Alterations in the peripheral blood were pronounced. The number of red blood cells varied characteristically from day to day and with a moderate increase (Figs. 5, 6). Although the total number of white blood cells showed daily wide variations, the average daily count for animals 1, 3, and 4 during thirty-one experimental days was only 6 per cent above normal (Figs. 5, 6). Changes in the leucocytic formula were the most pronounced and were characterized by an absolute and persistent increase in the number of lymphocytes and by an absolute decrease in neutrophils (Figs. 4, 5, 6). There were no changes in the number of other blood cell types from normal.

The developmental sequence of these alterations in the leucocytic formula can be easily discerned from the graphs, but it is desirable to point out, first, that there is an immediate rise in the number of lymphocytes, and that by the sixth experimental day the absolute number of lymphocytes may be from one and five-tenths to three times larger than the normal number (Figs. 5, 6); and second, that marked leucocytoses occur rhythmically in cycles which, with a fair degree

Fig. 2.—A graph of the daily alterations in weight and in the blood picture of the group I animals. Animals 1 and 2 were fed 1 grain of thyroid daily; animals 3 and 4 were fed 4 grains of thyroid daily.

Fig. 3.—A comparative chart showing the average daily rate of weight change in animals of experimental groups I, II, and III. A, second series of experiments which were not complicated by intercurrent infection; B, preliminary experiments in which pneumonia intervened; C, animal 3, the only group III animal to die of this particular treatment.

of accuracy, coincide phase by phase with the cyclic weight changes mentioned above, and that there is an even closer correlation between cyclic lymphocytoses and the weight changes (Fig. 6).

Group III: All but one of the group III animals receiving lethal doses of thyroid substance in conjunction with aleuronat lived for an indefinitely long time. Only animal 3 died during the course of experimentation, but it lived thirteen days. The exact length of time that the other animals could have survived this treatment is not known. Animals 1 and 6 received these drugs for thirty-one days, and animals 2, 4, and 5, for thirty-nine days, without showing evidence of impending death, and in immediately subsequent experiments performed on them, lasting from twenty to sixty days longer, death did not result (Fig. 1).

Fig. 4.—A comparative chart showing the average number of lymphocytes per cubic millimeter of blood per experimental day (diagonally lined columns) and the average normal number of lymphocytes per cubic millimeter of blood (stippled columns) of the animals of groups I, II, and III.

The animals in our preliminary group III experiments who contracted and actually died of pneumonia lived 16.5 days (Fig. 1B).

In this group the weight changes of every animal were basically alike, being characterized by three common alterations. (1) For a varying number of days each animal progressively lost weight, until about one-third of its original weight was lost. (2) This was followed by an indefinite number of days during which the body weight was stabilized and characterized by minor weight gains and subsequent losses to the basic low-weight level. (3) Weight loss occurred rhythmically in diphasic cycles occupying a varying number of days, usually three to seven. The first phase is characterized by either a slight loss or gain, or no change in weight, and the second by a marked weight loss exceeding the weight changes of the first phase whatever they may be (Figs. 7, 8). The col-

lective daily weight loss of animals 1, 2, 4, 5, and 6 was 3.5 Gm. Animal 3, which died in thirteen days, lost 6.9 Gm daily, which is double the weight lost by the others (Fig. 3A).

The average daily weight loss of our preliminary group III animals was 10 Gm. (Fig. 3B).

The number of red blood cells with daily variations increased above normal (Figs. 7, 8). There was much daily variation in the total number of white blood cells. The average white blood cell count of animals 1, 2, 4, and 6 during the course of experimentation was only 6 per cent lower than normal. Alterations in the leucocytic formulas of these animals showed the closest agreement possible. For the first few days (one to five) the number of lymphocytes remained near the normal level or slightly below it, but this period was followed by a marked rise in the lymphocytes so that, inclusive of both periods, the average number of lymphocytes per experimental day was 35.7 per cent above normal (Figs. 4, 7, 8). The neutrophils increased slightly during the first two days of experimentation, but they later decreased considerably below normal to a stabilized level. The average number of neutrophils per experimental day was 36.8 per cent below normal (Figs. 7, 8).

Animal 5, although unknown to us in the beginning, had a preexperimental existing pathology. Its total white blood cell count before experimentation was 12,960, of which 76.5 per cent were lymphocytes and 19.5 per cent were neutrophils. During the course of experimentation, the total white blood cell count was on the average 35.7 per cent below this animal's normal, but this was due mostly to a 29.3 per cent (in absolute terms 2,914 cells per cubic millimeter) decrease in the number of lymphocytes, and to a lesser extent by a 47.7 per cent (1,320 cells per cubic millimeter) decrease in the neutrophils. After suspension of the experimental feeding, the blood picture returned to the normal for this animal.

The total white cell count of animal 3 was reduced 12.2 per cent during the course of study. Alterations in the leucocytic formula were like those of animals 1, 2, 4, and 6 for the first six days, but on the seventh day the neutrophils increased to near the normal number, and for the remainder of the time that this animal lived, the leucocytic formula was practically normal.

In all animals of this group lymphocytoses occurred rhythmically in diphasic cycles which coincided phase by phase with concurrent cyclic weight changes (Fig. 8).

Our experimental method was built upon the proposition that if lymphocytes were functionally related to a hyperthyroid condition, an added concurrent stimulation of lymphopoieses and lymphocytosis in an experimental hyperthyroid state should mitigate the effects of this hyperthyroid state. Experimental bases of comparison were established by the experimental series of groups I and II.

Our group II series of experiments showed that aleuronat when taken by mouth induces a generalized lymphoid reaction in which a persistent and high lymphocytosis is characteristic of the peripheral blood. The exact *modus operandi* of aleuronat in effecting lymphocytogenesis is unknown, but it seems

Fig. 5.—A composite graph of the daily alterations in weight and blood picture of animals 1, 3, and 4 of group II which were fed aleuronat.

Fig. 6.—A graph showing the daily alterations in weight and blood picture of animal 3 of group II.

to be something of a toxic reaction. If weight loss may be used in this instance to indicate toxicity, it is evident that the aleuronat in the amounts given was only slightly toxic because the animals in this series actually gained weight during the greater part of these experiments which lasted thirty-two days, and when weight loss did occur, it was so slight and of such short duration that it seems negligible and to have little bearing on the final interpretation of our results.

Fig. 7.—A composite graph showing the daily alterations in weight and blood picture of animals 1, 2, 4, and 6 of group III which were fed thyroid and aleuronat.

Our group I series of experiments showed that the hyperthyroid state induced by the daily administration of 1 grain of thyroid substance causes death after three days of treatment; that death is preceded by marked daily weight losses, and by a progressive decrease in the degree of lymphocytosis on days subsequent to the first experimental day which varies directly with the amount of thyroid given. The latter phenomenon is subject to many interpretations, but we believe that the lymphocytes are "used-up" in some manner faster than they can be produced. We rather doubt that the reduction in the number of lymphocytes in peripheral blood is due to a premature death of the lymphocytes because of an increased metabolic effect of thyroxin, because thyroxin seems unable to increase metabolic activity of lymphoid tissue (Anselmino, Eichler, and Schlossmann⁹).

With this knowledge of the individual effects produced by the daily administration of 1 grain of thyroid and 1.5 Gm. of aleuronat, an interpretation becomes possible of the results obtained in our group III series of experiments, in which both of these drugs in the amounts just indicated were administered jointly. The results of these group III experiments showed that, although 1 grain of thyroid substance daily did induce a marked hyperthyroid state in these

Fig. 8.—A graph showing the daily alterations in weight and blood picture of animal 1, group III.

animals when administered in conjunction with aleuronat, the severity of the hyperthyrosis was considerably less than that produced when this amount of thyroid substance was given alone, as in group I. In view of the facts that all the animals in group III lived longer, and, with the exception of one animal, lived indefinitely longer than did those of group I; and that the rate of weight loss experienced by these animals was but a fraction of that of the animals of group I; and that even the animals of our preliminary group III experiments who contracted and actually died of pneumonia lived five times longer and lost weight more slowly than the animals of Group I; the inevitable conclusion is,

that the mitigation of the known potential fatal effects of 1 grain of thyroid substance when taken daily must have been due to the lymphocytogenic effect of the aleuronat, and that the lymphocytes constituted the means by which this mitigation was accomplished. It would seem that this inference is correct for several additional reasons. (1) In all group III animals there was an almost direct correlation phase by phase of cyclic lymphocytoses with cyclic weight losses which showed that when the number of lymphocytes increased, the rate of weight loss decreased; and when the number of lymphocytes decreased, the rate of weight loss increased. In group II such a correlation is also evident, for the rate of weight gain is greater when the number of lymphocytes increases; and conversely, when the number of lymphocytes decreases, the rate of weight gain decreases. (2) The only death occurring among the group III animals involved an animal whose hemopoietic system failed to respond as expected on the basis of the group II experiments to aleuronat stimulation. (3) Animal 5, group III, which before experimentation had an existent pathology requiring a high lymphocytosis was able to mitigate completely the fatal effects of lethal doses of thyroid substance even in the face of a persistent and lower degree of lymphocytosis which occurred during the course of experimentation. However, the total lymphocyte count of this animal, in spite of this reduction, was above that of the animals of group I and above that of animal 3 of group III which died because of a poor lymphocytic response. (4) In supplementary experiments on two animals in group III to test the effects of continued thyroid feeding alone, a lymphocytosis was maintained at a high level. (5) Death occurred in every instance when the time rate and degree of lymphopoietic response was less than the time rate and degree of development of the thyrotoxicosis. (6) It would seem further that the mitigation was due directly to the lymphocytes rather than to any reaction between aleuronat and thyroxine, or to the action of antihormonal substances, because two animals of group III which were fed thyroid in the absence of aleuronat for thirty days or longer in supplementary experiments showed no augmented thyrotoxic symptoms; and when the dose of thyroid was suddenly increased, death occurred as promptly as it did in those animals of group I.

CONCLUSIONS

(1) Aleuronat when taken by mouth, and in doses of 1.5 Gm. daily, induced a characteristic lymphocytosis in the blood of guinea pigs weighing between 300 and 500 grams each. This lymphocytogenic effect of aleuronat may have been due to the fact that the drug was slightly toxic.

(2) The daily feeding of 1 grain of desiccated thyroid substance to half-grown guinea pigs produced a thyrotoxicosis which was fatal in from two to four days.

(3) The daily feeding of 1.5 Gm. of the lymphocytogenic drug, aleuronat, in addition to a daily lethal dose (1 grain) of thyroid substance to half-grown guinea pigs either prevented completely or delayed the development of a fatal thyrotoxicosis. The evidence indicated that the living lymphocytes constituted the means by which this mitigation of the known potential fatal effect of daily 1 grain doses of thyroid was accomplished.

(4) The lymphocytes in thyrotoxic lymphocytosis are performing a function directly related to the alleviation of the thyrotoxicosis.

(5) It would further seem that the lymphocytic infiltration of toxic thyroid glands is an expression of this lymphocytic function.

A STATISTICAL STUDY OF TEMPERATURES IN HYPOGLYCEMIC COMA*

ESTHER BOGEN TIETZ, M.D., PH.D., CECILE NADLER, B.A., AND
EDITH KLEMPERER, M.D., CINCINNATI, OHIO

INTRODUCTION

THE use of hypoglycemic comas in the treatment of schizophrenic patients presents such striking clinical features that there is a temptation to generalize from observations during the treatments. This is particularly so if the observation is repeated in a number of different cases. One of the most significant physical changes induced by insulin hypoglycemia is low body temperature, the reading sometimes being below 90 degrees. The depth to which these temperatures will drop seems to vary greatly, but observations suggest that they bear some interesting constant features. It was noticed for instance that in some cases patients whose temperatures dropped very low during the early treatment periods did not reach such a low point during later treatments. It seemed, therefore, to be of some interest to determine whether a statistical analysis of a sufficient number of cases would yield any reliable data concerning this rise. We wished to determine whether it bore some definite relationship to the outcome of the treatment; whether it was related to the dosage of insulin used, or whether it was an individual expression of the patient treated.

*From the Longview State Hospital, Cincinnati, Ohio, and the Department of Psychiatry, College of Medicine, University of Cincinnati.

Received for publication, August 15, 1940.

This study was financed through the National Committee for Mental Hygiene from funds granted by the Committee on Research in Dementia Praecox founded by the Supreme Council, 33rd Degree Scottish Rite, Northern Masonic Jurisdiction, U. S. A.

Patients were observed carefully during each shock period and individual manifestations of the shock were recorded on a chart previously described.⁷ Dosage was regulated so that the patient was in coma at the end of three hours and had one hour of this for each treatment after the first ten treatments, which were usually less prolonged.

If the temperature drop during hypoglycemia is due to the size of the insulin dose, it may be that the compensatory rise depends on the adequacy of the autonomic centers to meet this strain. There is much to indicate that schizophrenic patients lack the ability to respond with such homeostatic mechanisms.^{3-5, 8, 9} That hypoglycemia induces a compensatory sympathetic activity has been indicated by many authors.^{1, 6, 10} We might expect, therefore, that the better patients would tend to be better able to combat the temperature drop; that as recovery took place the coma temperature would be closer to the normal temperature and the temperature would tend to keep constant regardless of the size of insulin dosage.

METHODS

In these studies the insulin injections were given at 6 A.M. and the patients were given glucose at about 10 o'clock or later. The temperature was taken at 10 o'clock before termination by means of glucose gavage. At this time most of the patients were in coma. Rectal temperatures were used throughout this study.

The daily 10 A.M. shock temperature records of 36 patients who recovered after insulin shock were studied. This group was considered "A" recoveries and will be referred to as group A throughout this study. Twenty patients who failed to show any improvement and are, therefore, designated as group D were likewise studied.

The first forty-five days were studied in each case since many patients were not treated longer than this. The first statistical study consisted of obtaining a mean of the 10 o'clock temperature, for all patients of each group, and for each day of the forty-five days.

The range of daily means for the coma temperatures of group A were from 96.79 for the first day of treatment to 97.02 for the forty-fifth day of treatment. Although the means did not show a steady course, there was a definite trend upward. In the D group, although the mean for the first day was 97.04 and for the last day 96.7, the daily means fluctuated so unsteadily that there was no constant trend.

When the temperatures were grouped for periods of one week or five days, the same trend was noticed. The averages for group A for the first and ninth weeks were 96.67 and 96.78, respectively. For the D group these means were 96.53 and 96.54. It must be remembered that each of these means represents five days' average for a large number of different patients. Although the trend upward in the A group may certainly be considered greater than that of the D group, there is statistically no reliable difference between the two.

A study of the units of insulin used for each treatment was then considered. Examining the amount of insulin used in the first dose (the shock dose), we find a mean of 104.03 for the A group, and a mean of 112.22 for the D group.

These differences are not reliable statistically. The shock doses of the two groups are approximately the same. Obtaining the means for the insulin given to the A group for each of forty-five treatments, we found the mean to be 104.03 on the first day of treatment and 76.1 on the forty-fifth day. In the D group these amounts were 112.22 to 83.33, respectively. There is a reliable difference between the dosage used at the beginning and end of treatment in group A, the insulin used being greatly diminished. In the D group the dosages were also diminished, although the difference is not as constant for all members of the group. On the whole, moreover, we note that the total insulin used on the A group for each of the forty-five days of treatment is less than that used on the D group.

TABLE I

DAILY AVERAGES OF INSULIN DOSE AND TEMPERATURES IN HYPOGLYCEMIC SHOCK

TIME OF TREATMENT	TEMPERATURE		INSULIN	
	MEAN	SIGMA	MEAN	SIGMA
<i>Group A, 36 Patients</i>				
1st day	96.79	0.98	104.03	44.5
45th day	97.02	1.17	76.11	42.9
1st week	96.67	1.22	110.7	46.2
9th week	96.78	1.33	75.2	41.7
<i>Group D, 20 Patients</i>				
1st day	97.04	1.10	112.22	61.4
45th day	96.7	1.61	83.33	54.8
1st week	96.53	1.38	118.7	68.7
9th week	96.54	1.71	83.1	52.7

It might appear that the rise in temperature observed in improved patients in the course of the treatment may be due to the greater decrease in the amounts of insulin used in this group during the treatments as compared to that of group D. In order to see whether this is true, partial correlations between day of treatment, insulin dosage, and coma temperature, were made. These correlations were found to be so low that it can be said that no correlation exists between insulin dose and temperature.

TABLE II

PARTIAL CORRELATIONS BETWEEN DAY, AMOUNT OF INSULIN, AND 10 O'CLOCK TEMPERATURE

<i>Group A, 1,364 Treatments</i>			
	(1) <i>Day</i>	(2) <i>10 o'clock Temperature</i>	(3) <i>Insulin</i>
Mean	23.15	96.6	77.3
Sigma	12.48	1.27	38.6
Correlation			
between (1) and (2)	$= 0.13 \pm 0.02$	(2) and (3) $= 0.02 \pm 0.02$	(1) and (3) $= -0.27 \pm 0.02$
<i>Group D, 796 Treatments</i>			
	(4) <i>Day</i>	(5) <i>10 o'clock Temperature</i>	(6) <i>Insulin</i>
Mean	22.67	96.46	94.7
Sigma	12.75	1.61	60.8
Correlation			
between (4) and (5)	$= 0.02 \pm 0.02$	(5) and (6) $= 0.06 \pm 0.02$	(4) and (6) $= 0.20 \pm 0.02$

A study of the temperature and insulin dose, considering all days for all patients of the A group compared to those of the D group, reveals some striking findings. The temperatures of those in group A were higher than those in group D. The reliability of this difference is 2.09, indicating a significant difference, which probably would be proved to be statistically reliable if more cases were considered. The amount of insulin used all forty-five days for patients of group A was less than that used in patients of group D, and this difference is statistically reliable.

DISCUSSION

We noticed that patients who recovered from schizophrenia after undergoing insulin shock therapy (group A patients) required less insulin during the course of treatment. This may suggest that patients requiring lower doses to induce shock may have a better chance of recovering than those requiring larger doses. On the whole, moreover, the group A patients do not reach as low temperature levels as do the patients who do not improve. Of interest is the demonstration in these studies that the group A patients show an increasing temperature during the course of treatment, with a tendency to return during insulin coma to normal temperature levels. The possibility suggests itself that this indicates an improvement in the homeostatic functions of these patients. That such improvement occurs has been suggested by other authors as demonstrated by improved blood pressure and other signs of cardiac functions.² It would be interesting if the probability of a good remission could be predicted during treatment by upward rise in the coma temperature curve. At any rate, the findings presented here indicate that the determination of temperature during insulin shock may be of definite importance beyond mere interest, and that the supposition that the temperature level observed during hypoglycemia is merely dependent on dosage of insulin is unfounded.

SUMMARY

1. Statistical studies of rectal temperatures taken during insulin coma are reported.
2. The range of daily means for 36 recovered patients showed a trend upward. Twenty unimproved patients showed no such rise.
3. Initial insulin shock doses were the same in both groups. There was a definite decrease in the daily insulin dosage used in the course of treatment, this decrease, however, being more constant in the A group.
4. We note, moreover, that the total insulin used on the A group is less than that used on the D group.
5. The rise of temperature in the course of treatment in the A group is not due to the decrease in the insulin dosage.
6. The temperature of the group A on the whole was greater than that of the group D.
7. The amount of insulin used for the group A patients for all the treatments was less than that used on the group D patients.

We gratefully acknowledge the unflinching support of Dr. E. A. Baber, Superintendent of Longview State Hospital, and his assistants, who conduct the Hypoglycemia Clinic.

SEROLOGIC DIAGNOSIS IN HISTOLOGICALLY PROVED CHRONIC SYPHILIS*

AN ANALYSIS OF 424 NECROPSIES

OSBORNE A. BRINES, M.D., AND BENJAMIN JULIAR, M.D.
DETROIT, MICH.

ONE frequently finds contradictory figures given as to the percentage of positive serologic tests in cases of various types of chronic syphilis. It was for this reason that it was decided to analyze the autopsy protocols of the Detroit Receiving Hospital for the period from January, 1928, to July, 1940, in order to determine the incidence of positive serologic reactions in the various forms of proved autopsy syphilis.

The serologic tests performed were as follows: previous to November, 1933, Kolmer and Kahn tests; from November 1, 1933, to January 1, 1934, Kolmer, Kahn, and Kline tests; and from January 1, 1934, to July 1, 1940, the Kline test was used as an exclusion test, and Kahn tests were performed on those sera which gave positive Kline reactions.

No attempt was made to determine the relative merit of the serologic tests employed. If any one test was positive, it was considered sufficient reason for recording the serology as positive for syphilis. Results were reported as positive, negative, or doubtful.

*From the Pathological Laboratories of Receiving Hospital, Detroit.
Received for publication, August 21, 1940.

In this study of autopsy protocols for the period mentioned, 555 persons with microscopically proved syphilis were encountered. However, of this group, only 424 patients had an accompanying serologic report. The remainder died in the admitting room or on the wards shortly after admission, and no opportunity was afforded of obtaining a specimen of blood.

TABLE I
SEROLOGIC REPORTS

	CASES	PER CENT
Positive	321	75.7
Negative	82	19.3
Doubtful	21	5.0
Total	424	100.0

Table I shows the serologic findings in the 424 patients included in the study. It is noted that 75.7 per cent of these gave positive serologic reports.

In attempting to compare the figures obtained at the Receiving Hospital with those frequently quoted, one finds that very often there is no common ground upon which this comparison can be made. Most of the figures cited in the literature are based upon studies of groups of living patients, whereas, the cases covered in this report were all proved by microscopic examination of autopsy material. Kolmer¹ contends that in 80 to 100 per cent of chronic syphilis the serology is positive, and Stokes² states that he found 67 per cent of 252 persons to have positive serology. However, these figures were not compiled from autopsied material.

In this series it is seen that in 82 of 424 persons the serology was negative; a further analysis of this group brought out the interesting fact that in 60 per cent of the 82 cases, only syphilitic aortitis was found at autopsy. This leads to the question: Does the presence of a positive serologic reaction depend upon at least a certain minimal involvement of the organs and structures, or do the accepted pathologic criteria of what constitutes syphilitic aortitis need revision? If the answer to the first part of the question is in the affirmative, it would seem when there is syphilitic involvement of several organs the percentage of positive laboratory tests for syphilis should be higher. Table II shows the results of such an analysis.

TABLE II
RELATION BETWEEN EXTENT OF INVOLVEMENT AND PERCENTAGE OF POSITIVE TESTS

	CASES	PER CENT
Only one organ involved (usually syphilitic aortitis):		
Positive	206	71.0
Negative	66	23.0
Doubtful	19	6.0
More than one organ involved:		
Positive	115	86.0
Negative	16	12.4
Doubtful	2	1.6

It can be seen that the incidence of positive tests in the group of patients with multiple involvement was 21 per cent higher than in those with a single organ involved, and that there was 14 per cent more in the former group

who gave a positive reaction than in the total group of 424 persons. This finding is far from conclusive, but, nevertheless, gives some basis for the contention that positive serologic evidence of syphilis is somewhat dependent upon the extent of demonstrable pathologic involvement.

CARDIOVASCULAR SYPHILIS

Cardiovascular syphilis formed a major portion of the material studied. Some evidence of cardiovascular involvement was found in a total of 335 patients, or 79.0 per cent. This figure is about 33 per cent higher than that given by Symmers,³ who found evidence of vascular system syphilis in only 56 per cent of the 314 cases he studied. In this series syphilitic aortitis was the most common lesion encountered, occurring in 303 patients, or 71.4 per cent of the total (424 patients), a figure which is closely comparable to the one given by Cecil,⁴ who maintains that syphilitic aortitis is present in 70 per cent of persons with chronic syphilis.

In analyzing the serologic reports of the cardiovascular syphilis group, it was found that 71.6 per cent gave positive serology. This figure is considerably below the one given by White,⁵ who states, that "the serum reaction for syphilis is generally positive, and strongly so in cardiovascular syphilis; sometimes in approximately 15 per cent of the cases it is negative." Kolmer¹ claims that in chronic cardiovascular syphilis 80 to 96 per cent of patients will give positive serology by his method. Moore⁶ found 85 to 95 per cent of his clinical cases to be positive. Christian⁷ found that about 80 per cent of patients with syphilitic disease of the aorta gave a positive Wassermann reaction.

SYPHILIS OF ALIMENTARY TRACT

Thirty-five patients (8.2 per cent) had a diagnosis of some form of syphilitic involvement of the digestive tract. Table III shows the distribution of such lesions.

TABLE III
SYPHILIS OF ALIMENTARY TRACT (35 CASES)

	POSITIVE	NEGATIVE	DOUBTFUL
Liver	21 (80.7%)	4 (15.3%)	1 (4.0%)
Pancreas	7 (77.7%)	2 (22.3%)	0
Esophagus	1	0	0
Midgut	1	0	0
Cecum	1	0	0

Syphilis of the liver constituted only 6.1 per cent of the 424 patients in this series. Symmers³ found the liver to be involved in 33 per cent of cases showing post-mortem evidence of syphilis. Brockbank⁸ found the above to be true in 58 per cent of his cases. Flexner⁹ found 88 cases of hepatic syphilis in 5,089 autopsies (1 per cent). McCrae¹⁰ demonstrated 46 cases in 3,300 autopsies (1.3 per cent). The reason for the marked disparity between the figures quoted and those obtained in this series is not apparent.

Since the number of cases of syphilitic involvement of the liver²⁶ is comparatively small, the percentage figures obtained are indicative rather than conclusive. A total of 80.7 per cent had positive serology. McCrae and Caven¹¹ found

that 80.4 per cent of 41 persons with syphilis of the liver, which had been successfully diagnosed and treated, gave positive Wassermann reactions originally. O'Leary, Greene, and Rowntree¹² found that 90 per cent of their patients with hepatic syphilis had positive Wassermann reactions. Their diagnoses were made for the most part on the basis of clinical impressions and the effect of therapeutic tests.

CENTRAL NERVOUS SYSTEM SYPHILIS

Numerically, the group with syphilis of the central nervous system was second only to that showing cardiovascular syphilis. One hundred and thirty patients, or 30.6 per cent of the total, were found to have some form of syphilitic involvement of the central nervous system. No doubt this figure is much lower than the actual incidence of involvement of the central nervous system, since permission for examination of the cranial cavity of the patient was frequently not obtained. Of this number, 85.4 per cent had positive serology. Included in this group were 57 patients with general paresis, 87.7 per cent of whom had positive serology.

The figures given in the preceding paragraph differ from those given in reports by some well-known authors. Cecil⁴ states that it is unusual and rare for the serology to be negative in syphilis of the central nervous system. Grinker¹³ found the blood Wassermann positive in 65 per cent of all patients with neurosyphilis and that it may fall as low as 50 per cent in the latent phases of the disease. Kolmer's¹ figures ranged between 70 per cent and 100 per cent in his groups of patients with syphilis of the central nervous system. In general paresis, Grinker states, the blood serology is 100 per cent positive. Moore⁶ found it 90 to 95 per cent positive. These figures are definitely higher than those found in the group of cases covered in this analysis.

SUMMARY

1. A total of 424 patients with microscopically proved syphilis encountered at autopsy were analyzed statistically. All of these had accompanying serologic examinations.

2. Of the entire group 75.7 per cent had positive serology.

3. The patients with multiple organs involved gave 21 per cent more positive reactions than those with only one organ involved.

4. A total of 335 patients (79.0 per cent) showed some evidence of cardiovascular involvement. Of these 71.6 per cent had positive serology.

5. There were 26 cases of hepatic syphilis. This amounted to only 6.1 per cent of all the cases. In 80.7 per cent of these the serology was positive.

6. One hundred thirty persons exhibited central nervous system involvement, and 85.4 per cent had positive serology. In 87.7 per cent of 57 persons with paresis the serology was positive.

CONCLUSIONS

1. The percentage of positive blood tests for syphilis for the entire group studied did not differ appreciably from that usually reported.

2. The percentage of positive reactions in cardiovascular syphilis was about 10 per cent lower than the figures that are usually given.

3. Demonstrable hepatic syphilis occurred 25 to 50 per cent less frequently than in many other series.

4. The percentage of positive tests in hepatic syphilis coincided closely with the experience of others.

5. The percentage of positive tests in general paresis was definitely below that found in other series.

THE DIAGNOSIS OF PERIPHERAL ARTERIAL OBSTRUCTION*

SAUL S. SAMUELS, M.D., NEW YORK, N. Y.

TRADITIONAL methods of examination for the diagnosis of peripheral arterial obstruction are becoming inadequate and uncertain because of the demand for more reliable and accurate information in this field of medicine. Sole reliance upon palpation of the dorsalis pedis pulse as the standard procedure in the diagnosis of circulatory disturbances in the lower extremities is rapidly losing its former worth.

Manual palpation of peripheral pulses may be misleading because of the following variable factors involved: (1) The skill and experience of the examiner. (2) Anatomical deviation in position of the peripheral arteries. (3) Edema or excessive adiposity of the extremities.

These objections apply not only to the dorsalis pedis pulse but also to the posterior tibial and popliteal as well. The familiar sight of a group of physicians in a vascular clinic disputing the presence or absence of a dorsalis pedis pulse is sufficient argument for the claim that individual skill and experience play a considerable part in this diagnostic procedure.

*From the Clinic for Peripheral Arterial Diseases, 4th Division, Bellevue Hospital, New York, and the Department of Arterial Diseases, Stuyvesant Polyclinic Hospital, New York.
Received for publication, August 22, 1940.

Occasional instances of congenital absence of the dorsalis pedis artery have been observed. In these cases there is usually compensatory enlargement of a branch of the peroneal artery which produces pulsation in the lateral portion of the foot.

In the presence of edema of the feet either from cardiorenal or from infectious cause, the dorsalis pedis and posterior tibial pulses may be completely impalpable, although the arteries are patent. In obese patients similar difficulties may be experienced, not only with the arteries of the feet but with the popliteal as well.

Palpation of the popliteal artery is attended with considerable difficulty, and often requires various aerobic manipulations in order to feel pulsation of the vessel adequately. The status of the digital and plantar circulation of the lower extremities is not accurately revealed by palpation of the dorsalis pedis or posterior tibial arteries alone. If both of these vessels are felt in an extremity there is no assurance that the arterial tree distally is also patent. To ascertain this fact other tests must be utilized.

The importance of the detection of peripheral arterial disease in its early stages is obvious. Any method of examination which will reveal the presence of organic changes in the most distal parts of the extremity should be utilized more frequently than has heretofore been the rule. At the same time the physician who has relied traditionally solely upon palpation of the dorsalis pedis artery should realize the limitations of this method.

It is well to re-emphasize the fact that an important diagnostic point in the organic peripheral arterial diseases is the ability to detect the organic changes. The presence or absence of superimposed vasomotor disturbances, particularly vasospasm, is of secondary importance in diagnosis, the primary consideration being the detection of structural arterial disease. The tragedy of delayed diagnosis was recently illustrated in a case of thromboangiitis obliterans in a physician. About eight years ago he experienced symptoms in his legs which suggested to him the possibility of thromboangiitis obliterans. A physician was consulted who, after feeling both dorsalis pedis pulses and using no other diagnostic procedure, concluded that there was no evidence of arterial disease and that smoking might be resumed. A few years later the physician submitted himself for a blood count, for the determination of which it was necessary to puncture the tip of the right index finger. The trauma thus induced resulted in a gangrenous ulcer which did not heal until a year and a half later. At the first sign of gangrene the patient presented himself for an opinion. The lower extremities were examined and revealed definite right plantar ischemia in addition to poor dorsalis pedis pulses and excellent posterior tibial pulses. Oscillometric readings were 3.0 at the left ankle and 2.0 at the right ankle. Although both radial and ulnar pulsations could be felt, there was moderate ischemia of the fingers of both hands on elevation and exercise. There was a gangrenous ulcer at the tip of the right middle finger about 1 cm. in diameter. The patient refused to stop smoking, and about a year later no pulses could be felt in either foot and the oscillometric reading at the left ankle had decreased to zero. Extensive gangrene of the right index finger soon developed as well as gangrenous lesions of the left big toe and heel.

It is clear that had the diagnosis been made at the first examination, and had the patient been sufficiently impressed with the importance of complete cessation of smoking, the present situation could have been avoided. The assurance of the original examiner was so great that there was no arterial disease because of the bounding dorsalis pedis pulses that the patient was offered a package of cigarettes and told to smoke as much as he pleased.

In 1929 I¹ proposed a new test for the determination of arterial occlusion in the distal vessels of the extremities. This procedure, based on earlier observations of Oehler and Parkes-Weber, has proved so reliable over a period of fifteen years that it must be considered of diagnostic importance and as an obligatory part of the examination before the diagnosis of arterial disease is ruled out. Kramer,² from his large experience at the Philadelphia General Hospital, says "a positive plantar ischemia is significant. Our experience with this simple procedure has been that when positive findings are obtained, the other function tests will usually indicate evidence of an impaired peripheral circulation." Again, "we have found that a positive plantar ischemia has nearly always been associated with occlusive vascular disease." Lewin³ also considers the test an important part of the routine examination for determining the circulatory efficiency of the lower extremities.

In carrying out the test the patient lies recumbent on the examining table, and the legs are elevated to an angle of about 60 degrees, supported on a stool or some other arrangement. While in this position the ankles are flexed and extended repeatedly for about a minute. During and immediately after the maneuver the soles of the feet are carefully examined in a good even light. In every instance of organic arterial disease, whether due to thromboangiitis obliterans, or arteriosclerosis obliterans, a characteristic pallor of the sole of the affected extremity will become apparent either during the motion of the feet or immediately afterwards. The pallor, or plantar ischemia, is usually in direct proportion to the degree of obstruction present. In incipient cases, particularly those with patent dorsalis pedis and posterior tibial arteries, the ischemia may be difficult to detect by the novice, but experience will soon help in judging relative differences in color.

In the more advanced cases no difficulty should be experienced in detecting plantar ischemia. A cadaverous pallor, which may involve the entire foot as high as the ankle or farther, becomes apparent almost immediately.

The same principle of inducing ischemia as a diagnostic method may be applied to the upper extremities. Elevation of the hand above the head with alternate opening and closing of the fingers will produce, after a few moments of this motion, a transient ischemia of the digits or hand deficient in blood supply. This test may be positive in incipient cases of organic arterial disease in which the radial and ulnar pulses can be felt. It is of more practical value than the modification proposed by Allen⁴ which merely serves to distinguish between closure of the radial or ulnar artery. The test here described is more suitable for detecting early involvement of the digital arteries of the upper extremities.

Temperature changes are usually very pronounced in organic arterial disease even in the earliest stages. As a rule, the ischemic extremity is cor-

respondingly colder than the uninvolved limb. Where the condition is bilateral both will be colder than usual, with proportionate differences in coldness dependent upon the degree of occlusion present. For ordinary clinical diagnosis instrumental measurements are not necessary for temperature determination, the palm or back of the hand being sufficiently sensitive. For precise measurements of the skin temperature, the Dermalor⁵ is preferred.

Fig. 1.—Hellige-Samuels pulsimeter.

OSCILLOMETRY

The observation of Cawadias in 1912 that the Pachon oscillometer was admirably suited to the study of arterial patency in the extremities opened up a new and interesting field. Visual observation of arterial pulsation was made available so that quantitative measurement of the pulse amplitude in the extremity could be easily determined. Furthermore, pulsation could be detected at points where by manual palpation the arteries were not accessible. The examining cuff could be placed at any point on the limb, and oscillations were recorded at that particular level, whereas by the manual method one is limited to only a few areas.

While the clinical diagnosis of arterial obstruction can be made without instruments, it is also true that a more accurate picture is conveyed by oscillographic determinations than by purely clinical methods alone. Other valuable information can also be obtained from the oscillometer. If one remembers that the pulsation obtained with the instrument represents the expansion of the main vessels only, deductions can be made therefrom concerning the state of the collateral circulation in the extremities in an indirect way. For instance, a negative reading at the ankle level indicates complete obstruction of the main arterial channel. This being the case, it follows, therefore, that the collateral circulation in the extremity must be very small. On the other hand, a positive reading at the same level indicates only partial occlusion of the main vessels and a correspondingly better collateral circulation. For prognostic study such observations are extremely important because a zero reading at the ankle level in a case

of arterial disease would naturally convey the impression that the ultimate recovery of gangrene, for instance, would be doubtful because of the poor collateral circulation. On the other hand, a positive reading gives more encouragement to conservative therapy with better chances for eventual healing.

Fig. 2.—Schematic drawing to show construction of pulsimeter. *D*, aneroid diaphragm; *M*, mechanism for transmitting pulsation to indicating hand *SH*; *S*, set screw for adjusting indicating hand to zero; *I*, *II*, air chambers separated by diaphragm *D*.

Likewise, in cases without ulceration and gangrene zero readings mean more difficulty in conservative treatment, a longer period of therapy to attain symptomatic relief, and a doubtful outcome as far as ultimate development of gangrene is concerned. Positive readings in these cases mean better therapeutic results and less chance for the development of gangrene.

The oscillometer has thus extended the possibilities in the field of peripheral vascular diseases and should be made more available so that more accurate studies can be made and more practical information can be obtained. One of the great hindrances to the more universal use of the instrument has been its comparatively high cost. To overcome this objection a simplified apparatus has been devised which does not entail a large financial investment. This apparatus, because of its primary purpose of measuring pulsation, is redesignated "pulsimeter."

By means of a short piece of rubber pressure tubing, either an aneroid or a mercury sphygmomanometer is attached to the upper nipple of the pulsimeter. One outlet of the arm band of the blood pressure apparatus is connected to the

rear nipple of the pulsometer. It is essential that all connections be absolutely tight, so that there will be no leakage of air. If the inflating bulb of the blood pressure apparatus or the rubber arm band or any parts of the connecting tubes are defective, or allow even the slightest loss of air pressure, the pulsometer will not operate properly.

Fig. 3—Method of applying pulsometer for ankle readings.

In carrying out an examination, it is essential that the patient lie flat, completely relaxed, with the head back and arms at the side. If the patient is not completely relaxed, the slightest muscular movement, such as lifting a hand, will cause deflections of the pulsometer needle, interfering with the proper operation of the apparatus. The arm band of the sphygmomanometer is carefully applied, as in taking blood pressure, to the part under examination. As a rule, the region just above the ankle gives the most information if the lower extremities are being studied. It is essential that the cuff be applied snugly, not too tightly and not too loosely. Caution must be taken that there are no kinks in the tubing after the cuff is applied.

After all connections are tight and the cuff is properly applied, the escape valve on the inflating bulb of the blood pressure apparatus is closed tightly and the entire system is inflated. By watching the sphygmomanometer, the pressure being applied can be measured. During inflation, the indicating hand of the pulsometer will rotate a few times. This does not interfere with the operation of the apparatus and should be disregarded until the final inflating point is reached. The pressure in the cuff is increased until it is reasonably sure that the patient's systolic pressure has been exceeded. For routine examinations, it is sufficient to inflate the cuff to about 200 mm. of mercury, as indicated on the sphygmomanometer dial. When this point is reached, the indicating hand of the pulsometer revolves slowly until the entire system becomes stabilized. It is necessary to wait a few moments for this to happen before readings are taken.

As a rule, a pressure of 200 mm. of mercury will completely obliterate all pulsations; therefore, the indicating hand will not oscillate. In order to estimate the maximum oscillation of the indicating hand, it is necessary to decrease the pressure in the whole system by about 10 mm. at a time. This is done by partially releasing the air escape valve on the inflating bulb. With each deflation, the indicating hand may again revolve once or twice. It is important

to allow the hand to stabilize after each reduction in pressure in order to obtain a reading. As the pressure in the apparatus is decreased in stages of 10 mm. of mercury, the oscillations of the indicating hand increase in amplitude, until a point is reached corresponding to the patient's systolic pressure. When this level is obtained, the maximum oscillation known as the oscillometric index can be read.

It is not necessary that the indicating hand remain at the zero point either before, during, or after an examination. If all oscillations are either to the right or to the left of the zero point, direct readings can be obtained. If the hand swings to both sides of the zero point, it is necessary to add the readings thus obtained to determine the oscillometric index. In other words, if the hand swings from 2 on the left side to 3 on the right, the oscillometric index is 5. Likewise, if the indicating needle swings from 2 on the left side to 7 on the right side, by subtraction an index of 5 is obtained. Similarly, if the needle swings from 2 on the left side to 7 on the left side, the oscillometric index is 5. An irregular pulsation will, of course, give irregular readings. In such a case, the maximum oscillation is recorded.

Interpretation of Oscillometric Readings.—It must be understood that the significance of oscillometric readings for diagnostic purposes lies not so much in the individual values obtained as in the comparison of readings between opposite extremities at the same level. In other words, if the oscillometric index at one ankle is 5 and at the other, at the same level, it is 2, this is evidence of abnormal arterial circulation in the extremity with the lesser reading. On the other hand, readings of 2 in each extremity at the same level may be normal for that particular individual. The normal range of readings in the extremities is as follows: just above the ankle, 1 to 10; calf, 3 to 10; popliteal region, 3 to 10; thigh, 4 to 20. In the upper extremities, at the wrist, 1 to 10; brachial region, 2 to 10; axillary region, 4 to 10. Again, it must be emphasized that this range is very wide and varies considerably with different individuals. It is only by comparing corresponding levels of the extremities that conclusions can be drawn concerning the patency of the arteries.

SUMMARY

Palpation of the dorsalis pedis pulse alone is an inadequate method of diagnosing organic arterial obstruction in the extremities. The test for plantar ischemia should be an essential part of every physical examination. A new simplified inexpensive oscillometer is described.

SENSITIZATION INDUCED BY TETANUS TOXOID, ALUM PRECIPITATED

HERMAN GOLD, M.D., CHESTER, PA.

THE recent publication of Cooke and his associates¹ has served to center attention on the problem of sensitization induced by immunization with tetanus toxoid. In their very interesting study, Cooke and co-workers found that allergic reactions occur particularly after the second injection of alum-precipitated toxoid due to sensitization induced mainly by the peptones of the Berna or Witte type present in the toxoid. They also showed that sensitization to the bacterial products of *Cl. tetani* may take place.

Because of the importance of Cooke's observations we deemed it advisable to investigate this problem to determine (1) the frequency of sensitization as proved by skin tests; (2) the incidence of clinical evidence of sensitization; and (3) the possible existence of any correlation between (1) and (2).

Sixty-six patients that had been, or were undergoing, active immunization against tetanus were subjected to skin tests with two lots of materials. Lot A was prepared by a commercial biological house that employs Berna peptone in the manufacture of its tetanus toxoid, and lot B was supplied by a house that uses Difco proteose in its toxoid. All dilutions of lot A materials were made with Glenney's buffered salt solution. Lot B materials were diluted with sterile physiologic saline solution.

The following testing solutions were used: (1) tetanus toxoid A diluted 1:100 and 1:10; (2) Berna peptone A diluted to contain 0.01 and 0.10 mg. of nitrogen per cubic centimeter; (3) veal broth A diluted 1:10; (4) finished tetanus bouillon A diluted 1:100 and 1:10 (this preparation was a veal Berna peptone broth that had been subjected to all the manufacturing steps employed in the production of tetanus toxoid A, except that it had not been inoculated with tetanus bacilli); (5) tetanus toxoid B diluted 1:100 and 1:10; (6) Difco proteose B diluted to contain 0.01 mg. of nitrogen per cubic centimeter; and (7) tetanus media B diluted 1:100 and 1:10.

All persons included in this study had been treated with tetanus toxoid alum-precipitated A. A few also received intranasal instillations of tetanus toxoid topagen A. They may be classified in eight groups according to their immunization history.

Group 1 consisted of 7 patients on whom skin tests were performed two days before and thirty-two days after they had received the first injection of 1.0 c.c. of tetanus toxoid, alum precipitated.

Group 2 consisted of 29 persons on whom skin tests were done seventy-eight days after they had received the first 1.0 c.c. injection of alum toxoid.

Group 3 consisted of 4 persons on whom skin tests were done 207 days after they had received the first injection of 1.0 c.c. of alum toxoid. Thirty-two days later they were injected with a second dose of alum toxoid. Recheck skin tests were done thirty-two days after the latter was given.

Group 4 consisted of 3 patients (Nos. 19, 20, and 36) on whom skin tests were done 1,045, 1,544, and 1,479 days, respectively (about three to four and one-half years), after they had each received two doses of alum-precipitated toxoid. A third dose of 1.0 c.c. of alum toxoid was administered to two of them (Nos. 20, 36) fourteen days and one day, respectively, after the first skin tests were done. Skin retests were performed thirty-five and twenty-five days, respectively, after the third injection.

Group 5 consisted of 6 persons. Four of them, patients 17, 18, 30, and 35, had received three injections of alum toxoid (0.5 c.c., 0.5 c.c. and 1.0 c.c.) before the first skin tests were performed. These tests were made 766 to 809 days (about twenty-six months) after the third dose of toxoid was given. A fourth injection of 1.0 c.c. of alum toxoid was administered to the 4 patients fourteen, ten, two, and one day, respectively, after the first skin tests were performed. The skin tests were repeated twenty-eight, thirty-two, thirty-two, and twenty-five days, respectively, after the fourth injection of toxoid. The fifth member of group 5, patient 22, was tested 792 days (about two years) after he had received three 1.0 c.c. injections of alum toxoid. Twelve days later he was given a fourth injection of 1.0 c.c. of toxoid. Skin retests were done thirty-five days later. The last member of the group, patient 21, had received four injections of alum toxoid (0.5 c.c. each) prior to skin testing. Thirty-seven months had elapsed between the last dose of toxoid and the first skin tests. Fourteen days after the tests were performed, this person received a fifth injection of 1.0 c.c. of toxoid. The skin tests were repeated thirty-five days later.

Group 6 consisted of 5 patients that had been immunized by the combined subcutaneous and intranasal routes.² Prior to the two daily intranasal instillations of tetanus toxoid topagen, patient 31 had received two injections (1.0 c.c. each); patient 34, 3 injections (0.5 c.c. each); patient 37, 5 injections (1.0 c.c., 0.5 c.c., 0.5 c.c., 1.0 c.c., 1.0 c.c.); patient 38, 3 injections (1.0 c.c. each); and patient 39, 3 injections (0.5 c.c., 0.5 c.c., 1.0 c.c.) of alum-precipitated toxoid. Skin tests were performed on the entire group 210 to 263 days after the last toxoid topagen instillation in the nose. One to four days later they all received an additional injection of 1.0 c.c. of alum toxoid. Skin retests were done thirty to forty-two days after this final injection.

Group 7 included 9 patients, 4 of whom had received two courses of three daily intranasal instillations of tetanus toxoid topagen. Four others obtained the same treatment, except that the second course consisted of only two daily instillations. The ninth person received two courses of two daily intranasal topagen instillations. The entire group was skin tested eighty-four days after the last nasal treatment. Thirty-two days later they were all injected subcutaneously with 1.0 c.c. of alum toxoid. Skin retests were done thirty-two days after this injection.

Group 8 consisted of 3 persons, 2 of whom received a single course of three daily topagen instillations in the nose prior to skin testing, while the third

patient got an injection of 1.0 c.c. of alum toxoid previous to the course of nasal treatment. Thirty-two days after the first skin tests were done, all 3 received an injection of 1.0 c.c. of alum toxoid. Actually 240 and 146 days, respectively, had elapsed between the last intranasal instillation and the final injection of toxoid. The skin tests were rechecked thirty-two days after the last injection.

SKIN TESTS

About 0.02 c.c. of each testing solution was injected intracutaneously, and the reactions were read at the end of fifteen minutes and twenty-four hours. The immediate reactions (fifteen minutes) were described as negative, doubtful, slight, moderate, and marked in accordance with the usual allergic practice.³ In the instances where half-hour readings were made, the reactions did not materially differ from those recorded at the end of fifteen minutes. The delayed reactions consisted of local induration with papule formation, erythema of varying degrees and swelling. In many cases these reactions did not subside until forty-eight to seventy-two hours had elapsed.

The 7 persons tested before immunization showed negative reactions. Of 40 patients tested one to six and one-half months (largest number done at two and one-half months) after the first injection of 1.0 c.c. of tetanus toxoid-alum precipitated (groups 1, 2, and 3), 20 gave positive reactions of the immediate or delayed type to one or more of the testing solutions, while 20 were negative. The reactions varied in intensity from slight (+) to marked (++++). Two persons gave slight immediate reactions to veal broth A 1:10. One person gave a slight immediate reaction to tetanus media B 1:100, while 2 others gave a similar reaction to the 1:10 dilution of this material. None of these patients showed delayed reactions to either the veal broth A or the tetanus media B. Two gave slight immediate reactions to Berna peptone A, 0.01 mg. of nitrogen per cubic centimeter. One of them also showed a positive delayed response. One showed a moderate immediate as well as a delayed reaction to this peptone. Three persons gave positive delayed reactions though their immediate response was negative. Fifteen gave positive immediate reactions to Berna peptone A, 0.1 mg. of nitrogen per cubic centimeter. They were recorded as one questionable slight (?), 13 slight, and one marked. Six of these patients also gave positive delayed reactions. One gave a positive delayed reaction to this peptone, although his immediate reaction was negative. Only 2 gave slight immediate reactions to the Difco proteose B, 0.01 mg. of nitrogen per cubic centimeter. Nine persons gave positive immediate reactions to tetanus toxoid A, 1:10; in 3 they were read as questionable slight (?), in 5 they were slight, and in one the reaction was marked. Six of these also gave positive delayed reactions. Three with a doubtful (\pm) immediate reaction gave a positive delayed response. Six gave a positive immediate reaction to tetanus toxoid B, 1:10. In three the reaction was slight, in 2 it was moderate, and in one it was marked. Three of these also gave positive delayed reactions. One gave a definite delayed reaction though his immediate response to the toxoid B was doubtful (\pm). The reactions to the finished tetanus bouillon A were in agreement with those obtained with the veal broth A and Berna peptone A.

Three subjects of group 3 were skin-tested thirty-two days after the injection of the second dose of toxoid. In 2 there were no evidences of skin sensitivity. In the third patient only slight positive reactions occurred at the sites of the tetanus toxoid A and B, 1:10, although before the injection of the second dose this person had shown positive reactions to veal broth, Difco proteose, and Berna peptone as well. We cannot account for this discrepancy. In three members of group 4 the skin tests were performed about three to four years after the second dose of toxoid was injected. Patient 19 gave a slight reaction to toxoid B. Patient No. 20 showed slight immediate as well as delayed reactions to tetanus toxoids A and B. Patient 36 gave slight immediate reactions to toxoids A and B and Berna peptone A, 0.1 mg. of nitrogen per cubic centimeter. The last two patients were retested thirty-five and twenty-five days, respectively, after a third injection of 1.0 c.c. of alum toxoid was given. Patient 20 then showed slight immediate reactions to toxoids A and B, and a marked reaction to Berna peptone A, 0.1 mg. of nitrogen per cubic centimeter. Delayed reactions were also present. On the other hand, patient 36 showed immediate marked reactions to both toxoids A and B, and a slight + reaction to the Berna peptone but no delayed reactions.

When skin tests were done two to three years after three to four injections of alum toxoid (varying doses) had been given to the 6 members of group 5, we found that patient 18 showed slight reactions to tetanus toxoids A and B, and that patient 35 showed a slight reaction to toxoid B. The rest of the tests were negative. When retested about one month after the injection of an additional dose of alum toxoid, 3 members of this group, patients 18, 35, and 22, showed slight immediate reactions to tetanus toxoids A and B. Patient 18 also gave a questionable slight reaction to Berna peptone A, 0.1 mg. of nitrogen per cubic centimeter and tetanus media B, 1:10. Also patient 30 showed a slight reaction to tetanus toxoid A, while patient 17 gave a similar response to tetanus toxoid B. The most interesting reactions were shown by patient 21. A marked immediate reaction was elicited by tetanus toxoid A and Berna peptone A, 0.1 mg. of nitrogen per cubic centimeter, while a questionable slight response was brought forth by tetanus toxoid B. Veal broth A and Difco proteose B were negative, and tetanus media B gave a slight reaction. Intense delayed reactions occurred at the sites of toxoid A and finished tetanus bouillon A. Similarly, patients 31 and 37 (group 6) showed slight reactions to toxoids A and B. Patient 37 also gave slight reactions to Berna peptone A and veal broth A. After the injection of an additional dose of alum toxoid, patient 31 also showed a slight reaction to Berna peptone A, 0.1 mg. of nitrogen per cubic centimeter. Also patients 34 and 38 (group 6) who before the final injection of toxoid had shown negative skin reactions, now gave positive reactions to toxoids A and B. Actually patient 38 showed a moderate reaction to toxoid B. Both of these patients showed delayed reactions. Patient 39 (group 6) remained negative, notwithstanding the four injections of alum toxoid and the three intranasal instillations of toxoid topagen that she had received. Skin tests performed on patients of groups 7 and 8 that received intranasal instillations of toxoid topagen were completely negative except in one. Retests done after the injection of 1.0 c.c. of alum toxoid were also negative. The exception, patient 6, who showed

slight reactions to toxoids A and B, had received an injection of alum toxoid prior to the topagen instillations. The absence of skin reactions in these two groups may be purely accidental, since none of the patients showed any evidence of sensitization even after the injection of 1.0 c.c. of alum toxoid.*

DISCUSSION

Ample evidence is provided by this study in support of the belief that sensitization is an extremely individualized process. Thus, while patient 65 (group 2) gave marked reactions after one single dose of alum toxoid, patient 39 (group 6) showed negative skin reactions after he had received four injections of toxoid and two daily intranasal instillations of toxoid topagen. It is also apparent that sensitization as demonstrated by skin tests occurs rather frequently following the injection of tetanus toxoid alum precipitated.

Particularly worthy of note are the reactions obtained in several patients. Thus patient 25 (group I) showed a slight reaction to tetanus toxoid A, 1:10, and a marked reaction to tetanus toxoid B, 1:10, but was negative to the rest of the test solutions. Positive delayed reactions were produced by both toxoids as well as Berna peptone A, 0.1 mg. of nitrogen per cubic centimeter. These results were confirmed on two subsequent retests. Patient 58 (group 2) showed a slight reaction to Berna peptone A and a moderate reaction to toxoid B, 1:10. The latter also gave a pronounced delayed reaction. The rest of the tests were negative. The same type of reaction to tetanus toxoid B was found in patient 36 (group 4) and in patient 38 (group 6).

These findings would indicate that sensitization to the toxoid protein or to bacterial proteins of *Cl. tetani* has occurred in these patients as a result of the injection of 1.0 c.c. of alum toxoid A. The difference in the skin reaction to toxoids A and B is probably due to differences in concentration of these proteins as found in the two toxoid preparations.

Patient 65 (group 2) gave a marked reaction to toxoid A, 1:10, and Berna peptone A, and a slight reaction to veal broth A and tetanus media B. He was negative to Difco proteose B. Also patient 21 (group 5) showed marked reactions to toxoid A and Berna peptone A, and slight reactions to toxoid B and tetanus media B. These findings would indicate the existence of sensitization to Berna peptone. Confirmatory proof is to be found in the large group of patients that gave slight positive reactions to this protein. It would appear that Berna peptone when present in the alum toxoid used for immunization sensitizes patients more readily than the Difco proteose. This is in agreement with Cooke's observation.

Delayed Reactions.—Patient 29 (group I) is of interest because she gave prominent delayed reactions to toxoids A and B and to Berna peptone A though the immediate reactions to these products were questionable slight positive. The peptone reaction was especially intense. These findings were confirmed on two subsequent rechecks. The mechanism of these delayed reactions is not clear. As expected this patient gave a negative passive transfer test.

It must be remembered that these patients did not develop any demonstrable antitoxin titer following the intranasal instillation of topagen. The latter is of value only as a repeat stimulus after a basic immunity has been established through the subcutaneous injection of one or preferably two doses of alum-precipitated toxoid.

Similar delayed reactions occurred in a number of our patients. They consisted of either erythema of varying size and intensity or a bright red area of raised induration with a centrally placed papule. Localized swelling of the soft tissues around the site of injection was usually present. Occasionally there was some itching. These delayed reactions began to fade after twenty-four hours and disappeared completely at the end of forty-eight to seventy-two hours. Parish and Oakley⁷ also noted "late" reactions "like those occurring after staphylococcus toxoid," but they were at their maximum about two hours after the injection of the testing products and faded completely during the next three hours. Cowles⁹ also noted in one immunized person a curious delayed reaction that came on in twenty-four hours.

At present we are unable to evaluate the significance of these delayed reactions. In many cases, an immediate response to the testing solutions occurred as well. The immediate type of reaction was proved by Cooke and associates to be mediated through sensitizing antibodies that circulate freely in the blood and which can be passively transferred to the normal skin (Prausnitz-Küstner phenomenon). We performed passive transfer tests with the serum of patients 21 (group 5), 25, and 29 (group 1) in accordance with the usual technique.³ Each serum was injected into the skin of three normal nonimmunized persons (0.1 c.c. in each site). Two of the three recipients gave positive reactions at the sites sensitized with the serum of patient 21 when tested with tetanus toxoid B, 1:100, Berna peptone A, 0.10 mg. of nitrogen per cubic centimeter, and tetanus toxoid A, 1:100. All three recipients gave negative reactions at the sites sensitized with the sera of patients 25 and 29.

Duration of Skin Sensitivity.—In the presence of positive skin tests the question arises as to their duration. Cooke reported that one person lost his marked sensitivity within six months. However, another person showed a marked urticarial wheal when retested with tetanus toxoid 1:10 eight months after the second dose had been injected. Passive transfer test with the serum then obtained was weakly positive. We retested patients 21 (group 5), 25, 29 (group 1), 58, and 65 (group 2) six months after the last tests described in the text were performed. At this time patient 21 showed no change in the immediate reactions, but there were no delayed reactions. Patient 25 showed negative immediate reactions to toxoid A and to Berna peptone, 0.10 mg. of nitrogen per cubic centimeter and a moderate reaction to toxoid B, 1:10. Similarly, there was a definite decrease in the size of the delayed responses which occurred at the sites of toxoid A and B and Berna peptone A. Patient 29 showed no change in the reaction to toxoid A, but there was a definite increase in the response to Berna peptone A and to toxoid B. The latter gave a marked reaction. Again the delayed reactions in this patient were very prominent, especially to the Berna peptone. Patients 58 and 65 showed no change in their reactions. On the other hand, the results obtained in the comparative skin tests of several patients suggest that skin sensitization may disappear with time. Thus the absence of positive skin reactions in patient 21 (group 5), when he was tested three years after he had received four injections of alum toxoid as contrasted to the marked reactions obtained one month after the fifth injection of toxoid, can be best explained on the basis that we are dealing here with reactiva-

tion of a sensitivity that had decreased with time. This explanation is more likely to be true than the alternate assumption that the first four injections of toxoid did not sensitize this person while the fifth one did.

Significance of Positive Skin Tests.—It is evident from our studies that a high percentage of persons immunized with tetanus toxoid alum precipitated that contains Berna peptone develop positive skin tests to the toxoid and its component constituents. But as in other fields of allergy, these skin tests to be significant must be correlated and associated with definite evidences of specific clinical sensitivity.

At the outset we were struck by the disparity between the high incidence of positive skin tests and the marked scarcity in our experience of untoward systemic reactions following the injection of two or more doses of tetanus toxoid alum precipitated. A review of the literature reveals a similar paucity of reports of allergic reactions induced by tetanus toxoid. In France where many thousands of men have been injected with three or more doses of Ramon's anatoxin, the procedure was reported as harmless, not being followed by any local or general reaction.⁴ In England Boyd⁵ also noted the absence of reactions. Recently two very interesting reports have appeared in the *British Medical Journal*. Whittingham⁶ reported two cases of anaphylaxis (nonfatal) that occurred among the 61,042 members of the Royal Air Force who had been immunized with two 1.0 c.c. doses of plain toxoid given about six weeks apart. The toxoid contained Witte peptone, which was held responsible for the severe peptone shock, since both patients gave positive skin tests to this protein. Whittingham summarized his experience as follows:

TOTAL NO. PERSONS INOCULATED	ACUTE ANAPHYLACTIC REACTION A	DEFINITE CONSTITU- TIONAL SYMPTOMS B	LOCAL REACTIONS ONLY C
61,042	2 patients (0.003%)	12 patients (0.02%)	651 patients (1.06%)
A. Anaphylactic shock.			
B. Influenza-like aching of head and body. Slight pyrexia. Seven of these persons had urticaria of limbs and body.			
C. Brawny swelling and pain for twelve to twenty-four hours. Twenty-two patients had urticarial swelling and itching around site of inoculation for a few hours.			

Parish and Oakley⁷ also reported one patient with anaphylaxis after the second injection among over 300 members of the staff of the Wellcome Laboratories that received two injections each of 1 c.c. of plain toxoid. The severe reaction was controlled by epinephrine. This patient had received two courses of staphylococcus toxoid, which has a high content of Witte peptone, two years and one year previous to the administration of the tetanus toxoid. This patient, as well as a number of persons who had received two injections of tetanus toxoid without showing any anaphylactic symptoms, gave marked skin reactions to Witte peptone and to peptic digests of beef, pork, and horse fibrin. Parish and Oakley stated that their observations "throw considerable doubt on the value of scratch and intradermal tests as usually interpreted on the basis of early readings." "Late" reactions appeared to be important. Because the patient in question was the only subject who developed mild anaphylactic symptoms soon after the 1:1,000 dilutions of Witte peptone and two other beef fibrin digests

had been injected intracutaneously, the authors felt that Witte peptone might have been the substance in tetanus toxoid to which the patient had become sensitive. They concluded that allergic phenomena, though alarming, appear to be rare and are readily controlled by the injection of adrenaline. It is important to remember that these two large series of cases were immunized with tetanus toxoid plain, which contains larger amounts of peptone than alum-precipitated toxoids. On the other hand, the latter may act as a better sensitizing agent.

In the United States tetanus toxoid alum precipitated has been used almost exclusively. In their report, Cooke and co-workers refer to two patients with urticaria besides our own case. The two cases were encountered by Hall after the injection of a second dose of toxoid (not alum precipitated). Since publication of Cooke's study, we have immunized 250 additional patients with two 1.0 c.c. doses of alum-precipitated toxoid A without a single systemic reaction. Three persons had severe local reactions which subsided in twenty-four to forty-eight hours. Because individual experiences are bound to be limited in scope, we have collected additional information through the kind cooperation of several workers in this field.⁹ This collective experience with tetanus toxoid alum precipitated is summarized in Table I.

Over 1,700 patients have been immunized with two doses of alum toxoid. Many received three injections. Only two cases of urticaria have occurred. One of them resulted after a number of injections had been given to an allergic child for hyperimmunization. The very small number of reactions in this large group of patients is in agreement with the experience of Whittingham⁶ and is in sharp contrast with Cooke's "belief that reactions occur more often than the present reports indicate." In his series of about 25 cases, Cooke and collaborators found four instances of induced sensitization with but one reaction of serious proportion. Actually there was only one patient with urticaria, while a second subject gave a very marked swelling with itching at the site of the second injection that subsided in twenty-four hours. In an addendum, Cooke stated that two additional cases of delayed urticaria were encountered. In one it occurred after the second dose; in the other, after the third injection. Neither case showed any significant skin test reaction to the toxoid (1:10) before or after the therapeutic injection.

From the data we have gathered it appears that following immunization with tetanus toxoid alum precipitated skin sensitization occurs much more often than clinical evidences of allergy. Actually the latter are a rather rare occurrence easily controlled by epinephrine hydrochloride. Moreover, an untoward allergic reaction may occur in the absence of any significant skin reaction (Cooke's two cases). Conversely, it does not follow that the presence of a positive skin test contraindicates the administration of tetanus toxoid. To insist upon a negative skin test before the injection of alum toxoid is given is not warranted by our experience. For example, among our own cases after significant positive skin reactions were obtained in two patients (Nos. 58 and 65, group 2), three months after the first dose of alum toxoid A had been given, they received a second dose without any mishap. Six months later these two patients were retested and again after obtaining marked skin reactions to tetanus toxoids A and B and Berna peptone A, a third dose of alum toxoid A was in-

TABLE I

DATA OF REACTIONS IN 1,700 PERSONS AFTER THE INJECTION OF TWO OR MORE DOSES OF TETANUS TOXOID ALUM PRECIPITATED (COLLECTED FROM THE LITERATURE AND PERSONAL COMMUNICATIONS FROM INVESTIGATORS IN THE UNITED STATES)

AUTHOR	NO. OF PATIENTS	NO. OF INJECTIONS	ALUM- PRECIPITAT- ED TOXOID	REACTIONS	SKIN TESTS
A. McBryde*	125 children	2	B and D	No allergic reaction. Occasional moderate severe local reaction	Not done
C. P. Brown*	100	50 had 2 50 had 3	C	None†	Not done
M. Fernan-Nunez*	500	2	D and C	None (remarkably free of reaction)	Not done
P. B. Cowles*	125	Most had 2 Good many 3	C and B	One student developed about 2° fever with headache and malaise after second injection. Subsidied during night	20† had skin tests done, with plain tetanus toxoid (bactopeptone) 1:500 saline dilution
R. Layden and W. W. Hall§	199	3	B	None	Not done
H. Gold	500	Most had 2 Many had 3 or more injections	470 had A 10 had B 10 had C 10 had D	One patient had generalized urticaria after second dose. Controlled by adrenaline	66 had skin tests done
A. F. Coetz*	180	2	B	118 had local reactions 17 had local and general reactions, the latter consisting of headache, anorexia, malaise, and occasional nausea 5 had only general reaction No allergic reactions were encountered	Not done
R. M. Kempton*	8	2	C	None	Not done

Tetanus toxoid alum precipitated A had Berna peptone.

Tetanus toxoid alum precipitated B had Difco proteose.

Tetanus toxoid alum precipitated C had Martin's peptone.

Tetanus toxoid alum precipitated D had Berna peptone.

*Personal communication.

†A physician reported that an allergic child had a constitutional reaction consisting chiefly of urticaria which occurred after a number of injections had been given for hyperimmunization. (For possible use as blood donor.)

‡Five-hundredths cubic centimeter was injected intracutaneously. Eight weeks after the second injection 3 students gave positive reactions and one in an hour or so. Of these positives one was a curious delayed reaction, similar to the others, but coming on in twenty-four hours. Several tests were made on this person with consistent results. Seven months after these tests, one of the mild reactors received 0.05 ml. of plain toxoid intradermally. Within fifteen minutes there developed an indurated zone about 3.5 cm. in diameter in an erythematous area 7.5 by 15 cm. The wheal persisted for eight hours while the erythema was visible the next day. When the erythema and induration were slight and transient -1 cm.² and lasting only for an hour or so, injections were given without mishap. There was no real reason, other than an excess of caution, for failing to give all reactors the usual recall injection.

5. Little practical value can be expected from routine skin testing before the injection of tetanus toxoid. This would only serve to render cumbersome an otherwise simple and effective method of immunization against tetanus. As in any other immunizing procedure, the occasional occurrence of an allergic reaction should be kept in mind and epinephrine hydrochloride, 1:1,000, should always be available.

I wish to thank Dr. W. A. Feirer, Director of the Medical-Research Division of Sharp & Dohme, and Dr. A. F. Coca, of the Lederle Laboratories, for the supply of testing solutions. I also wish to express my appreciation to Doctors A. McBryde, C. P. Brown, A. F. Coca, M. Fernan-Nunez, P. B. Cowles, and R. N. Kempton for allowing me to use their clinical data on persons actively immunized against tetanus.

LOCALIZATION AND CONCENTRATION OF STAPHYLOCOCCUS ANTITOXIN IN AREAS OF RABBIT'S SKIN*

R. H. RIGDON, M.D., MEMPHIS, TENN.

IN RECENT publications it was shown that staphylococcus antitoxin following an intravenous injection localizes and concentrates in areas of rabbit's skin where xylol is applied.^{1, 2} Foreign serum and antibodies have been demonstrated by others in areas of inflammation. Menkin³ showed the presence of horse serum following an intravenous injection in areas of inflammation by extracting the tissues in saline and using the precipitation reaction. Fox⁴ used a similar technique to demonstrate the localization and concentration of agglutinins in areas of inflammation.

The present paper is a report of some observations on the failure of dermal necrosis to occur in the rabbit when staphylococcus toxin is injected intradermally into areas where xylol has been applied in animals previously given staphylococcus antitoxin intravenously.

METHODS AND MATERIAL

Normal rabbits are used. They are carefully shaven twenty-four hours or longer before the experiment is begun. An area, approximately 4 by 6 cm., is outlined with India ink on one side of each rabbit. Five cubic centimeters of staphylococcus antitoxin is given intravenously in the marginal vein of the ear. Xylol, on a cotton applicator, is applied to the demarcated area of skin immediately after the injection of the antitoxin. One tenth cubic centimeter of staphylococcus toxin is injected intradermally in the xylol-treated and untreated skin of the same rabbit at intervals varying from immediately to nine days following the injection of the antitoxin.

In the control experiment xylol is applied similarly to the skin of six rabbits, and staphylococcus toxin is injected intradermally in each of two rabbits at the following intervals after the application of the irritant: five, twenty-four, and forty-eight hours.

The presence or absence of skin necrosis at the site of the injection of the toxin in the xylol-treated areas of skin is considered indicative of either the absence or the presence of antitoxin. The control for each experiment is the presence of necrosis at the site where the toxin is injected in the normal skin.

*From the Department of Pathology, University of Tennessee College of Medicine, Memphis.

Aided by grants from the John and Mary R. Markle Foundation and the University of Tennessee.

A portion of this work was done in the Department of Pathology, Vanderbilt University, Nashville, Tenn.

The staphylococcus antitoxin and the staphylococcus toxin were supplied by Lederle Laboratories.

Received for publication, August 23, 1940.

A marked variation in the size of the necrosis in each rabbit is also considered significant. Slight variations in the size of the necrosis may be observed when a series of injections of equal size are made in a single rabbit.

TABLE I

NECROSIS PRODUCED BY STAPHYLOCOCCUS TOXIN IN XYLOL-TREATED AND UNTREATED AREAS OF SKIN IN RABBITS GIVEN STAPHYLOCOCCUS ANTITOXIN INTRAVENOUSLY

RABBIT	TIME BETWEEN APPLICATION OF XYLOL AND INJECTION OF TOXIN	AREAS OF NECROSIS AFTER 24 HOURS	
		AREA WITH XYLOL	AREA WITHOUT XYLOL

*These rabbits received no antitoxin.

Rabbits given 5 c.c. of staphylococcus antitoxin.

All rabbits received 0.1 c.c. of toxin intradermally.

EXPERIMENTAL

The xylol-treated areas of skin become hyperemic and edematous within a period of minutes and continue to show macroscopic evidence of inflammation for approximately five days.

Staphylococcus toxin when injected intradermally produces necrosis in the normal skin within twenty-four hours. Table I shows the size of the necrotic areas in the xylol-treated and untreated skin when staphylococcus toxin is injected intradermally twenty-four hours previously. Furthermore, these data in this table show that all the rabbits in which xylol is applied to the skin and no antitoxin is given intravenously have areas of necrosis in the xylol-treated areas of skin approximately the same size as those in the untreated skin. There is also no significant difference in the size of the areas of necrosis in the treated and untreated areas of skin in those rabbits in which the toxin is injected intradermally immediately following the intravenous injection of the antitoxin.

The areas of necrosis in the normal skin are always smaller in the rabbits given antitoxin than they are in those rabbits given no antitoxin.

When the interval between the intravenous injection of the antitoxin and the intradermal injection of the toxin is two hours, complete inhibition of necrosis occurs in the areas of skin where the xylol is applied. There is also marked inhibition of skin necrosis produced by staphylococcus toxin when

xylol is applied from forty-four hours to five days following the injection of the antitoxin. After nine days the extent of the necrosis produced by the toxin in the area where xylol is applied is the same size as that which occurs in the untreated skin of the same rabbit.

DISCUSSION

The experiment shows that there is an absence of necrosis following an intradermal injection of staphylococcus toxin in those areas of skin where xylol is applied immediately after an intravenous injection of staphylococcus antitoxin when the toxin is given from two to forty-four hours later. This inhibition of local necrosis apparently results primarily from the neutralization of the toxin by the antitoxin. Staphylococcus antitoxin apparently accumulates in a greater quantity in the inflamed tissue than in the normal skin, as shown by the absence of necrosis in the xylol-treated areas. The presence and absence of necrosis in the skin of the same rabbit is a good control and eliminates the necessity of determining the variation in the normal staphylococcus antitoxin titer of each animal.

The size of the skin necrosis produced by staphylococcus toxin in the areas where xylol is applied apparently may be slightly influenced by factors other than antitoxin. This is shown by the slight variation in the size of the areas of necrosis produced by toxin in the rabbits treated with xylol twenty-four to forty-eight hours previously. Some of the staphylococcus toxin may be removed from the site of inoculation in the xylol-treated areas of skin as a result of an increase in the flow of lymph and blood. It is essential to inject the same quantity of toxin into the xylol-treated skin in rabbits given antitoxin as is necessary to produce definite areas of necrosis in the xylol-treated areas of the skin in the same animal without the addition of antitoxin.

It is interesting that an interval of approximately two hours is necessary before a sufficient quantity of antitoxin accumulates where xylol is applied to neutralize completely the amount of toxin used in this experiment. The antitoxic effect, sufficient to inhibit necrosis, remains in the tissue for a limited time only. This is shown by the presence of necrosis where xylol is applied, and the antitoxin is given five days before the intradermal injection of the toxin. Approximately equal size areas of necrosis occur in the xylol-treated and untreated skin when staphylococcus toxin is injected nine days after the xylol is applied locally and the antitoxin is given intravenously.

It would appear most likely that staphylococcus antitoxin localizes and concentrates in areas of tissue as a result of the same mechanism which permits colloidal dyes to localize and to concentrate in areas of inflammation. Staphylococcus antitoxin like trypan blue fails to localize and to concentrate in areas of inflammation when the antitoxin is injected twenty-four hours following the local application of xylol.¹

The concentration of antibodies in areas of inflammation may produce a local condition unfavorable for the development of an infectious process. Recently such a condition was thought to occur in mice passively immunized with staphylococcus antitoxin when they were given a subcutaneous injection of broth culture of staphylococci. There was a marked increase in the number of

leucocytes in the area of inflammation in the immune animals as compared with the number of leucocytes in the normal.⁵

It is conceivable that antibodies other than antitoxin may localize and concentrate in areas of inflammation provided there is an increase in capillary permeability. The favorable results obtained clinically by applying counter-irritants to local areas of inflammation produced by bacteria may be influenced by the localization of antibodies in the areas as a result of a local increase in capillary permeability.

It may be said that diphtheria antitoxin localizes and concentrates in areas of inflammation produced by the local application of xylol in the rabbit in a manner similar to that of staphylococcus antitoxin. No attempt has been made in these experiments to make a quantitative study on the localization of antitoxin in areas of inflammation.

SUMMARY

Staphylococcus antitoxin following an intravenous injection localizes and concentrates in areas of the rabbit's skin where the capillary permeability is increased through the local application of xylol. This localization of antitoxin is indicated by the development of a smaller area of necrosis where an intradermal injection of staphylococcus toxin is made into the xylol-treated skin. Antitoxin sufficient to inhibit necrosis localizes within approximately two hours and remains in the tissues for at least five days. The significance of the localization of antibodies in areas of inflammation and the use of counterirritants in the treatment of local infections are briefly discussed.

BACTERIEMIA PRODUCED BY AN AEROBIC, GRAM-NEGATIVE SPORULATING BACILLUS*

AMEDEO BONDI, JR., M.S., E. H. SPAULDING, PH.D., AND JOHN A. KOLMER, M.D.
PHILADELPHIA, PA.

DURING 1938 our laboratory isolated an aerobic gram-negative, spore-forming bacillus from the blood cultures of five hospitalized patients. Because this motile organism on primary isolation apparently did not contain spores or ferment carbohydrates, it was thought at first to be a member of the *Alcaligenes* group. Further studies, however, revealed its ability to form spores. In addition, it was found to have no serologic relationship to *Alc. faecalis*.

TABLE I
DATA REGARDING ISOLATION OF GRAM-NEGATIVE, SPORULATING BACILLUS

PATIENT	DIAGNOSIS	DATE	BLOOD CULTURE
S	Acute monocytic leukemia	6/27/38	Positive
		7/ 1/38	Positive
		7/ 7/38	Positive
		7/12/38	Negative
		7/20/38	Positive
H	Lymphocytic leukemia and pernicious anemia	7/16/38	Positive
		7/21/38	Negative
		7/23/38	Negative
C	Pneumonitis, tracheo-bronchial lymphadenitis	8/27/38	Negative
		8/30/38	Negative
		9/ 1/38	Positive
		9/ 8/38	Positive
		9/21/38	Negative
O	Undulant fever	9/14/38	Positive
		9/21/38	Negative
		10/ 7/38	Negative
B	Pneumonia	11/18/38	Positive
		11/22/38	Negative

A total of nine isolations were made over a period of five months (Table I). The blood cultures from three patients were positive once; from one other, twice; and from another, four times. In the last case the gram-negative bacillus was also isolated from the bone marrow and spleen at autopsy nine days after the last blood culture. Morphologically, biochemically, and tinctorially all five strains were identical, and there was but little doubt they comprised a single species. The consistency with which this bacillus was isolated in blood culture from one of these patients convinced us that we were not dealing with an ordinary contaminant, but with an actual inhabitant of the blood stream. Our purpose here is to submit the description of this bacillus and to report the results of serologic and pathogenic studies.

Received for publication, September 10, 1940.

DESCRIPTION OF ORGANISM

Morphology

Rods: 0.7 to 0.8 by 3.4 to 4.5 microns. Tapered with rounded ends. Occur singly and in pairs, never in chains.

Spores: Ovoid, 0.9 to 1.2 by 1.2 to 1.7 microns. Subterminal to central swelling of the rod, clostridial appearance. Often naked. Formed early (within 18 hours) at 37° C.

Motility: Active and progressive in young cultures. Peritrichous flagella.

Staining: Gram-negative. Young cells sometimes variable.

Cultural Characteristics

Colonies: On extract agar young colonies are medium-sized circular, entire, and regular. They are transparent, colorless, and glossy. Older cultures may contain a variant which is grayish white and opaque. Both types are often present, giving appearance of mixed culture.

Broth: Profuse growth in extract broth with fine pellicle, heavy sediment, and slight turbidity. Streamers often appear in broth.

Biochemical

Carbohydrates: No action on any of the common sugars, or salicin, mannitol, inulin, rhamnose, cellobiose, sorbitol, glycerol, raffinose, inositol, or dextrin. Starch not hydrolyzed.

Gelatin: Liquefaction in from 6 to 8 days at 37° C.

B. C. P. Milk: No coagulation, no acid, becoming alkaline in four to five days. No peptonization in seven days.

Nitrates reduced to nitrites to ammonia; indol negative; slight H₂S production in lead acetate agar. Grows in Koser's uric acid and sodium citrate media. No hemolysis on horse blood agar.

Growth Requirements

Temperature: Minimum temperature for growth, 25° C.; maximum, 50° to 55° C.; optimum, 37° to 42° C.

Optimum pH: Grows at a pH of 5.0 to 9.0. Optimum 6.0 to 8.0.

Inhibition by Dyes: Inhibited by dilutions of gentian violet not ordinarily affecting gram-negative organisms, namely, 1:200,000 to 1:400,000 on extract agar.

Thermal Resistance of Spores: Resists boiling water for 4 hours.

Oxygen Requirements: A strict obligate aerobe.

Antigenic Structure.—High-titered sera were produced by injecting rabbits with young, living, broth cultures. Cross agglutinations with flagellar antigens, as shown in Table II, indicate two serologic types. Strains H and S compose one type, while strains C, O, and B form a second. Reciprocal agglutination tests, using somatic antigens, showed a high degree of cross agglutination and suggested an O antigen common to both types.

TABLE II
RECIPROCAL AGGLUTINATION TESTS

FLAGELLAR ANTIGEN	SERUM DILUTION TITER			
	H	S	C	O
H	5120	10240	160	20
S	5120	10240	160	40
C	320	80	5120	10240
O	320	80	5120	10240
B	160	160	2560	2560

Pathogenicity.—None of the isolations was pathogenic for rabbits. On two different occasions rabbits were injected intravenously with 1.0 c.c. doses of undiluted broth culture on alternate days for a period of two to three months. There were no ill effects. Blood cultures were repeatedly negative. Certain rabbits were sacrificed, and cultures made from the liver, spleen, and kidney. All were negative. Since two isolations (S and H) were from cases of leucemia, daily blood counts were carried out. No significant change in the blood picture was observed.

Comparison With Dubos' Bacillus.—Recently (1939, 1940) Dubos reported the isolation of a bactericidal substance from a soil bacillus (B. G.) which, when first described, appeared to resemble our organism. Morphologically and biochemically they are somewhat similar, but they differ in that Dubos' organism hemolyzes blood and produces spores of low heat resistance. There is no serologic relationship.

One strain of each agglutinative type was fractionated by Dubos' method for obtaining gramicidin. At the same time a search was made for a similar bactericidal substance obtained by Hoogerheide (1940) from members of the *B. subtilis* group. All attempts were unsuccessful.

DISCUSSION

An attempt to classify this gram-negative, spore-bearing bacillus has met with little success. *Bergey's Manual* (1939) contains numerous species of the genus *Bacillus* which, in many respects, resemble our organism. Nevertheless, of the species described in sufficient detail for accurate comparison, every one is different from the organism being reported in some major morphologic or biochemical characteristic. We believe, however, that an attempt to create a new species would be unwarranted without extensive serologic investigation.

The source and significance of this bacillus is open to conjecture. There is no evidence that it acts as a primary, or even a secondary, incitant of disease. Its presence in the blood stream seemed to bear no relationship to the condition of the patients. No evidence was obtained that the number of organisms in the circulating blood at any one time was high. In addition, of the two sera tested (S and H) neither one contained specific antibodies. The highly resistant nature of the spores suggested that they might be found in saline, or on syringes and needles due to faulty sterilization. In this way, their presence in the blood stream could be explained.

Examination of several lots of glucose solution, saline, and syringes, however, did not yield this organism. The intestinal tract has been considered as a possible source. Nevertheless, cultures from stools of normal individuals were

consistently negative, although from one stool a spore-bearing bacillus of similar morphology was isolated. Each patient whose blood yielded this organism appeared to have lowered resistance. This may account for the survival and possible multiplication in the blood stream of an avirulent spore-former.

Although the literature contains a number of reports of the isolation of *Alc. faecalis* from blood (Andrieu and others, 1936), not all give an adequate description of the organism (Brown and Stewart, 1935; McIntyre, 1936; Goldberg, 1938). It is conceivable that in some of these instances the organism was actually this gram-negative spore-bearer, but due to the absence of spores on primary isolation from the blood stream it was mistaken for *Alc. faecalis*.

SUMMARY

1. An unidentified gram-negative, spore-bearing bacillus was isolated from the blood stream of five different patients.
2. From one individual the organism was isolated four times, from another twice, indicating a state of bacteriemia rather than external contamination.
3. The morphologic, biochemical, and serologic characteristics are presented.
4. The source and significance are discussed.
5. Any relationship to the B. G. organism of Dubos was ruled out. Search for a bactericidal substance by the methods of Dubos and of Hoogerheide was unsuccessful.

The generous assistance of Miss Frances Tuerffs in carrying out the pathogenicity studies is acknowledged with gratitude.

SEPARATION OF THE COAGULANT FROM THE TOXIC PRINCIPLES OF THE VENOM OF THE AUSTRALIAN TIGER SNAKE (NOTECHIS SCUTATUS)*

WITH REMARKS ON THE MODE OF ACTION OF THE COAGULANT

SAMUEL ROSENFELD, M.D., AND JOSHUA RUBINSTEIN, M.D.
BROOKLYN, N. Y.

THE venom of the Australian tiger snake (*Notechis scutatus*) is one of the most powerful snake poisons known. Injected subcutaneously, it is more potent per milligram than any other known snake venom.¹ Death is attributable to the action of an extremely active neurotoxin.² Tiger snake venom also contains a powerful coagulant substance. Very minute amounts can rapidly clot oxalated or citrated blood in vitro or cause intravascular coagulation in vivo on intravenous injection.^{3, 4} Only the venoms of the South American vipers, the jararaca (*Bothrops jararaca*) and the fer-de-lance (*Bothrops atrox*), and the Australian black snake (*Pseudechis porphyriacus*) are comparable in coagulating power. This property of tiger snake venom has been utilized clinically to arrest severe capillary hemorrhage by topical application.⁴ The coagulant action of snake venoms has led also to their introduction into the study of problems concerned in blood coagulability, and has served to increase our knowledge of this process.^{5, 6} It has been found that the coagulant factor of tiger snake venom produces its effect in the same way as does thrombokinase, except that the presence of calcium is not required; in other words, it can in itself activate prothrombin to thrombin.^{5, 6}

A great deal of work has been done in attempting to separate the coagulant from the neurotoxic factor of tiger snake venom, but hitherto only the toxic factor has been successfully separated.^{7, 8} In the present investigation a simple method has been devised to separate the coagulant from the toxic factor of tiger snake venom. It is based on the action of hydrochloric acid upon the venom.

A 1:1,000 solution of powdered tiger snake venom in physiologic salt solution (0.85 per cent NaCl) is made. The solution is filtered through ordinary filter paper to clear it of any debris. Hydrochloric acid, in strength of 1.4 normal or 5 per cent, is added in equal volume. After several minutes an opalescence is noted, which at the end of one-half to one hour forms a precipitate. The resulting mixture is allowed to stand overnight in a refrigerator. The next day the mixture is centrifuged at 2,500 to 3,000 r.p.m. for twenty minutes in order to get a well-packed layer of the precipitate and to effect complete separa-

*From the Division of Hematology, Department of Laboratories, the Jewish Hospital of Brooklyn.

Received for publication, September 11, 1940.

tion from the supernatant fluid. The supernatant fluid, which contains the toxin, is carefully decanted or pipetted so as not to disturb any of the sediment in which the clotting factor is present in an inactive state. An extremely small particle of sediment carried over into the supernatant solution will cause the fluid on neutralization to exhibit a significant degree of clotting power. The fluid is, therefore, filtered through a special grade of filter paper (Whatman No. 42), or through a No. 4 Jena fritted glass crucible. The sediment (precipitate) is broken up and dissolved in distilled water. The volume is made up to that of the original venom solution. It is then reprecipitated with 1.4 normal acid. After waiting one-half to one hour the precipitate and the supernatant are separated as before. The processes of precipitation and separation are again repeated. The three precipitations are necessary to free the coagulant present in the sediment from the small amount of absorbed toxin.

The sediment obtained after the third precipitation is separated by centrifuging as before, and then broken up and dissolved in a volume of distilled water equal to half the volume of the original venom solution. It is now carefully neutralized to a pH of 7.0 to 7.2, or to the pH of the original venom solution. The volume is then brought up to that of the original venom solution with distilled water and is ready for testing. It is essential that the resulting solution shall be water clear. If the solution shows any opalescence it will be much less potent in coagulant activity than a clear solution. During the process of neutralization a heavy precipitation occurs at about a pH 6.5, which may be the isoelectric point of some substance in this preparation. It is important to pass over this point quickly; otherwise a final clear solution may not be obtained.

The three supernatant solutions after filtration are neutralized to pH 7.2, and tested for clotting action. The volumes and any additions are recorded for calculating the dilution of toxin. They are then tested for possible clotting action upon fresh citrated human plasma. Usually no clotting takes place, and the fluids are ready to have their toxicity tested. Occasionally a weak coagulant activity may be noted. When this occurs, the fluids must be treated once with an equal volume of 1.4 normal hydrochloric acid to precipitate the clotting factor, which is then separated as above. The fluids after neutralization are now certain to be coagulant free.

TOXICITY OF THE FRACTIONS

Toxicity tests are made by subcutaneous injections into mice weighing from 15 to 20 Gm. In such animals the average minimal lethal dose of tiger snake venom acting within twenty-four hours is approximately 0.5 c.c. of 1:100,000 solution, or 0.005 mg. It was found that subcutaneous injections of the first supernatant solution, appropriately diluted, killed mice in amounts between 0.75 and 1.0 c.c. of 1:100,000 dilution, which is close to the lethal action of tiger snake venom. The small difference in degree of toxicity between the first supernatant solution and the whole venom solution is mostly accounted for in the toxicity of the second supernatant solution, which was lethal in amounts of 2 c.c. The third supernatant fluid has no significant amount of toxin when injected in doses as large as 3 c.c., the maximal amount of any fluid that can safely be injected at one time in a 15 to 20 Gm. mouse.

In testing the toxicity of the thrice-precipitated fractions (which contain the clotting factor) various preparations were made from amounts of whole venom up to 15 mg., which is equivalent to 3,000 minimal lethal doses in mice. Subcutaneously, inoculated as neutralized solutions in volumes of 2 to 3 c.c., these preparations were found to be harmless. Such mice were observed for a period of one month without their showing any ill effects.

Fig. 1.

THE COAGULANT ACTION OF THE PRECIPITATED FRACTION*

For testing the clotting power of the precipitated fraction, which contains the coagulant factor, a rack of small tubes was set up, each containing 0.1 c.c. of progressive dilutions of the fraction, each tube having one-half the strength of the preceding one. Considering the dilution of this fraction, when the volume

*The term "thromboid" has been applied by us to the precipitated fraction of tiger snake venom solution because of its seemingly thrombinlike action upon citrated plasma without the addition of calcium.

is brought up to that of the original venom solution, to be 1:1,000, the resultant final titers after 0.4 c.c. of citrated human plasma has been added to each tube, ranged from 1:5,000 to 1:1,280,000. Control tubes were set up with similar dilutions of the tiger snake venom from which the fraction was made. It was noted that up to the titer of 1:100,000 the coagulant fraction was just as powerful as the parent substance (tiger snake venom), with clot formation taking place between thirty and ninety seconds, depending on the dilution. In higher dilutions, however, the coagulant fraction rapidly becomes weaker as compared to the whole venom; thus, at a dilution of 1:300,000 the clotting time is twice as long for the fraction as it is for the whole venom. It would, therefore, seem that there is some destructive action by action upon tiger snake venom in the separation of the coagulant factor. It must be borne in mind, however, that the latter was not dried and weighed, and it is reasonable to assume a more powerful action for the coagulant fraction if this were done.

Clotting tests were also made with a purified fibrinogen solution, prepared by triple precipitation with sodium chloride of Berkefeld-filtered citrated plasma.⁶ When tiger snake venom or its coagulant fraction is added to the fibrinogen, no coagulation takes place, indicating that these reagents do not act like thrombin. But the addition of prothrombin, prepared by the action of carbon dioxide upon Berkefeld-filtered citrated plasma,⁹ enables clotting to take place readily. Hence it appears that tiger snake venom and its coagulant fraction act like thrombokinase, rapidly activating prothrombin into thrombin, without the need of calcium. However, the addition of calcium produces a greater acceleration of the coagulation time. This conception of the thrombokinase-like activity of tiger snake venom and of the coagulant factor derived from it is in agreement with the previous findings of Mellanby⁵ and Eagle.⁴

It is interesting to compare the clotting action of tiger snake venom and its derivative coagulant with the potent coagulant venoms of *Bothrops atrox* (fer-de-lance) and *Bothrops jararaca*.^{*} Up to a 1:5,000 titer, jararaca venom has a greater clotting activity than tiger snake venom or its derivative, but then it quickly loses its superiority and at a dilution of 1:10,000 and beyond it is distinctly weaker. The action of fer-de-lance venom closely parallels that of jararaca venom (see Fig. 1). The coagulant activity of still another venom—that of the Russell viper—appears to be far inferior to any of the above-mentioned venoms.

When jararaca or fer-de-lance venom is added to a pure fibrinogen solution, rapid coagulation takes place, indicating that these venoms, unlike tiger snake venom or its derivative, exhibit a thrombin activity.

In comparing the nature of the clots formed by the various venom coagulants, it was found that those produced by tiger snake venom and its derivative are firm and difficult to dislodge, whereas the venoms of the *Bothrops* group produce softer clots, which easily slide down the side of the tube when the latter is inverted. Furthermore, the clots of the *Bothrops* group undergo lysis within twelve hours, while those formed by the tiger snake venom and its derivative do not become fluid until after forty-eight hours.

^{*}For the separation of the coagulant from the toxic factor of the *Bothrops* group of venoms, the method described in this paper is not suitable. For the jararaca venom a method has already been devised.¹⁰

SUMMARY

A method has been described for completely separating the coagulant from the toxic factor of the venom of the Australian tiger snake (*Notechis scutatus*). Neither of the fractions was prepared in a dry state, nor was any attempt made to determine its chemistry.

The coagulant fraction is approximately equal in potency to its parent substance up to dilutions of 1:100,000, but in still higher dilutions there is a deterioration in the potency of the fraction. Injected subcutaneously into mice, the coagulant factor prepared from as much as 15 mg. of tiger snake venom, which is equivalent to 3,000 minimal lethal doses, is harmless.

The toxic fraction of the venom not only has no significant coagulant activity but also retains almost quantitatively the toxicity of the original venom.

In its action both tiger snake venom and its coagulant fraction behave like thrombokinase plus calcium, readily converting prothrombin to thrombin. They, therefore, readily clot citrated plasma. Unlike the *Bothrops* venoms, which have a thrombin action, they do not clot purified fibrinogen solutions; however, they will do so when prothrombin is added to the fibrinogen.

STUDIES ON THE DETECTION OF ABSCESSES AND TUMORS*

III. CONCENTRATION AND DETECTION OF A RADIOACTIVE SUBSTANCE IN ABSCESSES

H. H. KROLL, B.S., S. F. STRAUSS, M.D., AND H. NECHIELES, M.D., PH.D.
CHICAGO, ILL.

IN AN EARLIER paper a new method for the detection of abscesses or tumors was described. It consisted of the injection of substances which localize in or around abscess or tumor tissue.¹ These substances were made artificially radioactive and their localization was detected by a sensitive electron counter, which registered the points of highest concentration of gamma rays in the body. The blue dye T 1824 was employed. Its concentration in abscessed and normal tissue and various organs was described, and a theory on the mechanism of the localization process, based on physicochemical interpretations, was proposed.² Since the purpose of this work was to prepare a radioactive substance, which would localize preferentially in abscess and tumor tissue, and thus be available for diagnostic purposes in man, our attention was turned to other dye derivatives in order to find a more suitable carrier for the radioactive atom.

The various dyestuffs which have been used for studying localization phenomena are mainly vis-azo acid dyes containing three to five sulfonic acid groups. In various studies made on these compounds in order to correlate chemical structure and physiologic activity, the number of sulfonic acid groups in the molecule plays an important role.^{3, 4} The most readily available sulfonic acid derivative related to the bis-azo dyes is the disodium 1-amino 8 hydroxy 3,6-disulfonate (H acid), which is used as an intermediate in the preparation of trypan blue and other acid azo dyes. H acid has been found to have an affinity for serum proteins⁵ and also to localize in mouse carcinomas.⁶

Because of the ease of bromination, H acid was used in the investigation described in the present paper. It was brominated in aqueous solution, with inactive or with radioactive bromine, and these solutions, after the proper preparation, were injected intravenously into dogs having an abscessed thigh. The localization of the brominated H acid was determined by chemical analysis, while the concentration process of the radioactive compound was followed in the live animal by a Geiger-Mueller counter according to a method described in a previous paper.¹

Experimental.—Disodium 1-amino 8-hydroxy naphthalene 3,6-disulfonate was obtained from Eastman Kodak Co. The sodium salt was recrystallized from water, and a 1 per cent solution was used. The bromination of the H acid,[†] injection into the experimental animals, and chemical analysis of the tissues were

*From the Department of Gastro-Intestinal Research, Michael Reese Hospital, Chicago.

†The bromination of H acid in aqueous solution is accompanied by an oxidation to a 1,4 naphthoquinone derivative.

carried out by methods already described,² except that in the present experiments the calculated amount of silver acetate was added to the solution, which was heated to boiling to coagulate the silver bromide, and the solution was centrifuged and filtered to remove the precipitate. All free bromide ions were removed by this procedure.

The radioactive bromine, a mixture of the several possible isotopes, was generated from active lithium bromide by oxidation with potassium bromate. The lithium bromide was activated by exposure to a deuteron beam by means of the cyclotron.

Chart 1.—Distribution of monobrominated H acid in the bodies of dogs.

The calculated amount of lithium bromide and potassium bromate required to monobrominate the H acid was dissolved in 10 to 15 ml. of water and placed in a modified distilling flask connected with a condenser. Three milliliters of 6 N sulfuric acid were added, and the reaction mixture was warmed gently. The bromine was distilled quantitatively into the flask containing the H acid. The bromination proceeded instantaneously, and the reaction was complete when the bromide-bromate solution became colorless, indicating that the lithium bromide had been completely oxidized. The brominated solutions thus prepared were treated in the same manner as the inactive preparations. Extreme care must be exercised to avoid contamination which would produce an increased count in the Geiger-Mueller apparatus.

The localization of the radioactive compound in the experimental animals was determined by the following procedures: An artificial abscess was produced in the thigh as described previously,¹ and twenty-four hours later the animals received an intravenous injection of the preparation; twenty-four hours later they were anesthetized by nembutal, and the following sites of the dog

were focused on the Geiger-Mueller tube: abscessed thigh, normal thigh, lower chest, upper chest, and head. The average total number of counts in a series of three-minute interval readings was used as a measure of the radioactive material concentrated in a given region. The Geiger-Mueller tube is so designed and shielded that the radiations which it may detect must come from the limited area studied. The radiations detected from the radioactive regions of the animal were primarily gamma rays.

TABLE I
CHEMICAL ANALYSIS OF TISSUES AND ORGANS*

SAMPLE	MG. OF BR PER 100 GM. OF WET TISSUE		
	GRAMS OF MONOBROMINATED H ACID INJECTED		
	0.2	0.4	0.6
Abscess thigh	1.80	2.60	2.90
Normal thigh	0.70	0.90	1.20
Kidney	1.80	2.10	3.60
Spleen	1.70	2.20	3.00
Liver	1.60	2.00	2.90

*Animals sacrificed twenty-four hours after injection. The data listed here are the averages obtained from four animals for each concentration studied.

Data.—Table I tabulates the results of the chemical analysis of the tissues and various organs when 0.2, 0.4, and 0.6 Gm. of monobrominated H acid were injected. These data are illustrated graphically in Chart 1. The optimum concentration of monobrominated H acid on the basis of these results is the 0.4 Gm. level. With this dose, the concentration in the abscess was slightly higher or equal to the concentration found in spleen or kidney. At the 0.6 Gm. level the amount of bromine found in the spleen and kidney was greater than that found in the abscess. On the basis of the above results, 0.4 Gm. of H acid was used in the study made with the radioactive compound. The results of the localization of the radioactive H acid are given in Table II.

TABLE II
DISTRIBUTION OF RADIOACTIVE MONOBROMINATED H ACID IN FOUR ANIMALS FOLLOWING
INTRAVENOUS INJECTION OF 0.4 GM.

SITE OF COUNT	AVERAGE COUNT PER THREE-MINUTE INTERVAL			
	PREPARATION A		PREPARATION B	
Control*	16	19	22	19
Abscess	57	125	106	105
Normal thigh	31	54	53	51
Lower chest	68	96	133	121
Upper chest	65	109	105	90
Head	54	112	85	64

*Background count due to cosmic and other radiation.

The conclusion drawn from this series of experiments corroborates the chemical analysis. The region of the lower chest, occupied by the kidney and spleen, has a slightly higher concentration of radioactive material than the abscessed thigh in 3 of 4 experiments.

DISCUSSION

The experiments described, although still in the experimental stage, illustrate a new application of the artificially radioactive elements namely, as diag-

nostic indicators for regions of infection. There are many instances where a knowledge of the location of a focus of infection would be of the utmost importance to the surgeon. The preliminary studies made on the location of the brominated H acid in inflamed tissue partly realize this aim, although more experimental work must be done before the use of these indicators may be applied clinically.

The problems to be solved before clinical investigations become possible are (1) the preparation of suitable carriers for the radioactivation; (2) an extensive study of the localization of these carriers in various types of inflammation, tumor growths, and tissue abnormalities; and (3) the technical improvement of the Geiger-Mueller counter so that it may be easily handled and focused on limited areas. It is expected that once the various phases of research listed above are carried to a successful culmination, the radioactive isotope and the Geiger-Mueller counter will prove to be a valuable tool in the hands of the diagnostician.

SUMMARY

The bromination of disodium 1-amino 8 hydroxy naphthaline 3, 6-disulfonate with normal and radioactive bromine is described.

The localization of the inactive brominated derivative in abscess and normal tissue, spleen, kidney and liver, after intravenous injection of varying concentrations, was determined by chemical analysis. The concentration of the radioactive material was determined by locating the regions of highest radioactivity in the live animal by a Geiger-Mueller counter. The application of radioactive isotopes in the diagnosis of tissue abnormalities is discussed.

We want to express our gratitude to Doctors Simon and Slotin from the Department of Chemistry, the University of Chicago, for preparation of the radioactive lithium bromide.

STUDIES IN ABSORPTION OF UNDIGESTED PROTEIN*

IX. ABSORPTION FROM THE STOMACH AND ESOPHAGUS

MAX HARTEN, M.D., IRVING GRAY, M.D., SAUL LIVINGSTON, M.D., AND
MATTHEW WALZER, M.D., BROOKLYN, N. Y.

THE absorption of traces of unaltered protein occurs physiologically in fasting adults and children within a relatively short period after oral administration of the protein meal.¹ In studies by Brunner and Walzer² fish protein appeared within fifteen minutes after its ingestion in the circulation of 93.8 per cent of the patients tested. In one instance, fish protein was detected in the blood stream two minutes after the consumption of the fish meal. The rapid absorption of other proteins, such as egg,³ peanut,⁴ and cottonseed⁵ in an unaltered state, has also been demonstrated. Such absorption occurs regularly, not only following the ingestion of these substances but also following their administration by tube into the duodenum,⁶ into the ileum and colon,⁷ and into the rectum.⁸

Whether absorption of unaltered protein can occur from the stomach has long been a moot question.⁹ In a study of 3 patients with gastric carcinoma with incomplete pyloric obstruction, Gray and Walzer⁴ found the absorption rates to be considerably retarded in every instance. This retardation was attributed to mechanical interference with the passage of the ingested protein into the duodenum. Because of the pathologic changes of the gastric mucous membrane in these cases, no conclusions applicable to the normal stomach could be drawn from the investigations.

Further study of the question of gastric absorption was sought by comparing the absorption rates of peanut protein following oral and intraduodenal administration in a series of 14 selected patients.⁹ Averages of 24.3 minutes and 18.6 minutes, respectively, were obtained following the oral and intraduodenal administrations of the protein meal. If it could be assumed that no absorption occurred from the stomach or esophagus, the average delay of five or six minutes associated with oral administration might be accounted for as the time needed for the passage of protein from the stomach into the duodenum in amounts sufficient to be absorbed from the small bowel. Previous experimental studies, however, did not eliminate the possibility that absorption of protein might be taking place from the stomach as well as from the small intestine. The need for further information on the subject of absorption from the stomach and esophagus, therefore, became apparent.

Received for publication, September 21, 1940.

As a result of the pioneer work of Straus it was found that the immunologic technique which had been previously employed to study the absorption of unaltered protein in human beings could be applied effectively to similar studies in the rhesus monkey.¹⁰ This opened up new possibilities for experimental investigation of problems in absorption which had not been feasible in the human being. The present studies were, therefore, undertaken to investigate the question of absorption of unaltered protein from the stomach and esophagus in the rhesus monkey.

TECHNIQUE

The technique employed in these experiments was that described by Straus and Walzer in a previous communication.¹⁰ A cutaneous site on a rhesus monkey was sensitized by the intracutaneous injection of a human serum containing skin-sensitizing antibodies (atopic reagins) for the antigen to be studied. After an interval of from twenty-four to forty-eight hours to permit fixation of the antibodies at the cutaneous site, the specifically related antigen was administered orally. The lighting-up of the sensitized cutaneous site with an urticarial reaction within a few minutes marked the entrance of unaltered protein into the circulation.

The *sensitizing serum* in these experiments was obtained from an asthmatic patient, "P," who manifested marked positive reactions to intracutaneous tests with dilute cottonseed extract. This serum showed an unusually high titer in atopic reagin content for cottonseed protein (1:1,024 by the dilution method of Coca and Grove).¹¹ To effect local cutaneous sensitization about 0.05 ml. of the undiluted human serum was injected intracutaneously on the thigh or chest of the monkey. An interval of one or two days was then allowed to elapse before the absorption experiments were performed. Food was withheld from the animals for at least twenty-four hours previous to the experiment, but small amounts of water were given. The *protein test meal* consisted of a cottonseed "milk" which was made by mixing 10 Gm. of raw ground cottonseed in 30 ml. of tap water. The method of administration of the test meal and the amount employed varied with the experiment. The *absorption time* was the interval which elapsed between the administration of the test meal and the onset of the reaction at the sensitized cutaneous site.

ABSORPTION OF COTTONSEED PROTEIN FROM THE STOMACH

Experiment I.—This experiment was designed to determine whether or not absorption can occur from the stomach in the rhesus monkey. The animal employed in this study was a female monkey, weighing 4 kg. The details of the experiment are presented in their chronologic order as follows:

November 5, 1937. 9:00 A.M. A cutaneous site on the left chest of the monkey was passively sensitized to cottonseed antigen with an intracutaneous injection of 0.05 ml. of "P" serum.

November 6, 1937. 9:30 A.M. Two grains of veterinary nembutal were administered intravenously. Immediate narcosis resulted.

10:00 A.M. The abdomen was opened. Two clamps were placed at the pyloric end of the stomach. The stomach was completely sectioned between these clamps. The clamps were left in situ.

10:07 A.M. A rubber catheter was introduced into the stomach through the nose. Thirty milliliters of cottonseed "milk" was then injected, through the tube, into the stomach.

10:18 A.M. Wheal formation started to develop at the sensitized cutaneous site, indicating the absorption of the cottonseed protein into the circulation.

The *absorption time* of the cottonseed protein from the stomach in this animal was eleven minutes.

Experiment II.—Before definitely concluding that the positive result obtained in the foregoing experiment was based on absorption of the antigen from the stomach, it was necessary to exclude the esophagus as a possible site of absorption. In this experiment, therefore, the stomach was "isolated" from the esophagus as well as from the duodenum. A male monkey, weighing 3.5 kg., was used in this study.

November 27, 1937. 9:00 A.M. A cutaneous site on the left thigh of the monkey was sensitized to cottonseed with "P" serum.

November 28, 1937. 9:30 A.M. Narcosis was induced by the intravenous injection of 2 grains of nembutal.

9:35 A.M. The abdomen was opened. Two clamps were applied just below the cardio-esophageal orifice, and the stomach was completely sectioned between these two clamps. Just proximal to the pyloroduodenal junction the stomach was completely sectioned between two clamps applied at this site. All clamps were left in situ.

9:56 A.M. Fourteen milliliters of cottonseed "milk" were injected by syringe directly into the lumen of the stomach, through a fine needle penetrating the gastric wall. The stomach was only partially filled by this test meal.

9:58 A.M. Wheal formation started to develop at the sensitized cutaneous site, marking the entrance of cottonseed protein into the circulation.

The *absorption time* of the cottonseed protein from the stomach in this animal was two minutes.

ABSORPTION OF COTTONSEED PROTEIN FROM THE ESOPHAGUS

Experiment III.—This experiment was designed to determine whether or not absorption can occur from the esophagus in the rhesus monkey. For this experiment a male animal, weighing 4.2 kg., was used.

December 3, 1937. 9:00 A.M. A cutaneous site on the right thigh of the animal was passively sensitized to cottonseed with "P" serum.

December 5, 1937. 9:20 A.M. Narcosis was induced with 2 grains of nembutal, injected intravenously.

9:30 A.M. The upper and the lower ends of the esophagus were exposed. The lower end was sectioned between two clamps placed proximal to the cardio-esophageal junction. The upper end was similarly sectioned between two clamps placed approximately one-half inch below the pharyngo-esophageal junction. The clamps were left in situ.

9:56 A.M. The clamp at the upper end of the esophagus was momentarily released, and 7 ml. of cottonseed "milk" were introduced into the esophagus through its exposed upper opening. The clamp was then replaced in its original position.

10:06 A.M. A positive reaction started to develop at the sensitized cutaneous site, indicating the entrance of the cottonseed protein into the circulation.

The *absorption time* of the cottonseed protein from the esophagus in this animal was ten minutes.

DISCUSSION

The experiments were performed on the monkey because these studies obviously could not be done on man. In previous investigations,¹⁰ however, it has been repeatedly demonstrated that the phenomenon of absorption of unaltered protein in the monkey closely simulates that observed in human beings. Moreover, the experimental studies^{7, 12} on mucous membrane hypersensitiveness after passive local sensitization have also shown remarkable similarities in both man and the monkey. Under the circumstances, it is reasonable to assume that the absorption of unaltered protein from the "isolated" stomach and "isolated" esophagus observed in the monkey could be demonstrated in human beings under similar experimental conditions.

Attention has been called to the findings revealed in a previous study on human beings that the average absorption time following oral administration of antigen is longer by five or six minutes than the intraduodenal rate.⁶ In the light of the present experiments this difference in absorption rate, which might be assumed to be the time needed for the protein to pass from the esophagus and stomach into the duodenum, is now subject to another interpretation. The possibility must be entertained that under certain circumstances the absorption time following oral administration of the antigen may represent the rate of absorption of unaltered antigen from the stomach and even from the esophagus. At any rate, this route of entry of unaltered antigen into the circulation cannot be excluded as a possibility when the antigen is taken orally. In fact, the experimental evidence now at hand indicates that antigens may be absorbed from any part of the alimentary tract, though the rate of absorption may vary somewhat in the different organs.

The amount of antigen necessary to produce the allergic reaction has been shown to be infinitesimally small. In man, Brunner and Baron, in unpublished experiments, have demonstrated that the intravenous injection of cottonseed extract containing 0.0001 mg. of nitrogen is sufficient to induce a reaction at a cutaneous site previously sensitized with the serum used in the present experiments. Using the same serum in experiments on monkeys we, in unpublished experiments, have found that the intravenous injection of cottonseed extract containing 0.0002 mg. of nitrogen was usually sufficient to elicit a reaction at a sensitized cutaneous site. It is obvious, therefore, that only minute amounts of protein need be absorbed into the circulation to produce a reaction at a passively sensitized site. From the point of view of clinical allergy, however, these traces of absorbed unaltered protein may be sufficient to produce severe and even fatal reactions in sensitive patients.

CONCLUSION

The absorption of unaltered protein has been experimentally demonstrated to occur from the esophagus and from the fasting stomach in the rhesus monkey.

THE IDENTIFICATION OF *BLASTOMYCOIDES HISTOLYTICA* IN THREE INFECTIONS OF THE CENTRAL NERVOUS SYSTEM*

REBECCA A. HOLT, M.A., RICHMOND, VA.

Synonyms: *Torula histolytica* (Stoddard and Cutler, 1916), *Cryptococcus histolyticus* (Freeman and Weidman, 1923), *Torulopsis histolytica* (Castellani and Jaco, 1933), *Debaryomyces hominis* (Vuillemin-Todd and Herrmann, 1936).

THE presence of *Blastomycoides histolytica*¹ (Stoddard and Cutler, 1916), or a closely allied species, has been reported according to Magruder² as the causative agent in 66 cases involving the central nervous system, of which three were found at the University of Virginia Hospital. Recently, Gray³ added two more cases which occurred in South Africa, and Goldberg added an-

*From the Department of Bacteriology and Parasitology, Medical College of Virginia, Richmond.

One other probable unreported case of a histopathologic diagnosis of Pusch, but was not confirmed from the neurologic standpoint by Dr. James Asa Shield in a separate paper. These cases will be reviewed from the neurologic standpoint by Dr. James Asa Shield in a separate paper.

Received for publication, September 25, 1940.

at the Medical College of Virginia. was made in 1933 by Dr. Lewis C. Freeman.

other one in New York. I wish to report here the bacteriologic and pathologic data on three other cases, bringing the total number* of recorded cases in the literature to 72, and that in Virginia to six.

Since the chaos in the nomenclature of the yeastlike organisms causing these infections has been deplored by Shaw† and others, the synonyms listed above are given. Shaw has pointed out also that not as many species exist as are now recorded and stressed the importance of recognizing their protean manifestations. Further, a review of the literature revealed the fact that seldom has there been a complete bacteriologic description of this yeast accompanying the histologic and clinical studies on the same case, although very adequate cultural or tissue descriptions on separate cases have been made.

CASE 1.—In this case studied by us, *Blastomycoides histolytica* was demonstrated in post-mortem sections and cultures, and was confirmed by mouse experiments as suggested by Crone and associates,‡ in order to standardize a routine procedure for diagnostic purposes. No ante-mortem bacteriologic work was done, although a routine urinalysis showed the presence of yeastlike cells, which were not identified. The clinical diagnosis was that of a brain tumor.

Pathologic Studies:‡ A post-mortem examination was permitted on the head only. No gross pathologic findings suggested torulosis. Microscopic examination of the piaarachnoid tissue showed a marked diffuse cellular infiltration. These infiltrating cells were small round cells and epithelioid-like cells with finely granular eosinophilic cytoplasm and eccentrically placed vesicular lobulated nuclei. There tended to be paravascular granulation tissue nodules composed of the above cell types, both in the meninges and about the vessels within the brain tissue proper. The epithelioid-like cells formed an inner zone about the vessel, while the round cells formed an outer zone. Multinucleated giant cells with eosinophilic cytoplasm containing round clear bodies were found in these nodules. About the vessels in the basal ganglia were "cystlike" areas made of numerous round bodies with doubly refractile borders and a central ground glass substance when stained with hematoxylin and eosin. With Gram's stain these bodies took a deep blue color and were identified as yeastlike cells, probably torula. There was no cellular reaction in these areas. These bodies were also found in the subarachnoid tissue where about them was a marked cellular reaction, focal areas of diffuse hemorrhage, and phagocytosis of some by the above-described multinucleated giant cells (Fig. 1.).

Bacteriologic Studies: A routine culture on blood agar plate of a meningeal swab taken at autopsy revealed, after forty-eight hours, a mucoid, colorless growth. Microscopically, the presence of yeastlike organisms was noted with many budding forms and well-defined cell walls. Transplants on Sabouraud's media and corn meal agar plates showed sufficient growth at room temperature within forty-eight hours for preliminary studies. The growth on corn meal agar always appeared white. On Sabouraud's agar early growth was cream-colored, later becoming yellow, then brown. A mucoid consistency of early colonies was gradually lost. No fermentation of dextrose, lactose, saccharose, maltose, mannite, inosite, arabinose, or xylose occurred. Gelatin was not liquefied. No differences were seen in cultures grown under reduced oxygen tension from those not submitted to this atmosphere. Microscopically, gram-positive, round, and oval budding forms, 4 to 6 microns in diameter, with thick cell walls were observed. No ascospores, capsules, or mycelium were demonstrated (Fig. 2).

Animal Experiments: Six mice were injected intraperitoneally with 0.5 c.c. of saline suspension of a seventy-two-hour culture on Sabouraud's agar at room temperature. The density of the injection suspension was equivalent to standard No. 3 on MacFarland's

*Since the acceptance of this paper for publication, six additional cases¹⁰ of torula infection of the central nervous system have been reported.

†Personal communication from Dr. Frederick W. Shaw.

‡Published with the approval of Dr. Frank L. Apperly, Department of Pathology, Medical College of Virginia, Richmond.

nephelometer. Seven days later an apparently normal mouse was killed. Yeastlike organisms were found in the viscera, lung, heart, brain, and cord as proved by direct smears, cultures, and histologic sections. Grossly and microscopically, no marked changes of the tissues were noted. On direct smears pleomorphism of the organisms (2 to 12 μ diameter) and capsule formations (0.5 to 1.0 μ thickness) were observed, but no ascospores or mycelium. *Blastomycoïdes histolytica* was recovered in the cultures of the vital organs listed above, with

Fig. 1.—Section of human brain. Organisms within giant cell. Hematoxylin and eosin stain ($\times 2,200$).

Fig. 2.—Smear preparation of forty-eight-hour culture on Sabouraud's agar from human meninges. Gram's stain ($\times 2,200$).

similar growth characteristics of the primary cultures. Four of the remaining inoculated mice died within the following three weeks. The gross and microscopic pathology of yeast meningitis, with a generalized infection characterized by gelatinous tumors with slight inflammatory reactions, marked endothelial hyperplasia, foreign body giant cells, "cystlike" areas, and occasional caseation was seen. *Blastomycoïdes histolytica* was recovered again by

cultural means. The sixth mouse was killed after four months, although it appeared normal. No gross or microscopic pathology was noted, and no organisms were seen on direct smears. *Blastomycoides histolytica* was recovered, however, in cultures of the lung and liver. Neither agglutinins nor precipitins were demonstrated in the sera of rabbits immunized against antigens prepared as were those of Benham,⁵ and Lamb and Lamb⁶ (Figs. 3 and 4).

Fig. 3.—Section of mouse brain showing organisms in meningeal exudate. Hematoxylin and eosin stain ($\times 2,200$).

Fig. 4.—Section of mouse lung. Hematoxylin and eosin stain ($\times 2,200$).

CASE 2.—This case was diagnosed as meningitis due to yeast infection on March 23, 1938. The patient received specific treatment with iodides and was dismissed. Since then she has remained in apparent good health, except for the blindness which developed during the illness.

Bacteriologic Studies: The first isolation of yeastlike organisms was made from the spinal fluid by cultural means similar to those already given. No animal experiments were run at this time.

Recently upon readmission of this patient to the hospital for observation, the presence of the same yeast was shown in urine and spinal fluid as proved by mouse inoculations with pathologic studies and cultures to be *Blastomycoides histolytica*. Results of the blood, sputum, and stool cultures were negative. No agglutinins or precipitins were demonstrated in the patient's sera.

CASE 3.—Until *Blastomycoides histolytica* was isolated from two specimens of spinal fluid just prior to death, clinically this case was thought to resemble more closely tuberculous meningitis, although no acid-fast bacilli were found on smear preparations or in cultures. Only ante-mortem bacteriologic studies were made, since an autopsy was not granted.

Bacteriologic Studies: The identification of *Blastomycoides histolytica* in two specimens of spinal fluids was accomplished by the same procedures as previously given. In direct microscopic studies no familiar budding forms were seen, although ill-defined lymphocyte-like cells with thick refractile walls were noted in moist preparations and smears stained by Gram's method. The demonstration of acid-fast bacilli was accomplished neither by microscopic examinations nor by cultures on Miraglia's and Petragnani's media. Growth of *Blastomycoides histolytica* was inhibited on Petragnani's media containing malachite green, although it was profuse on Miraglia's at 37° C. Fungous and acid-fast cultures on the urine collected just before death proved negative.

SUMMARY

The increasing number of reports of yeast infections of the central nervous system, especially in Virginia, lead us to believe the condition not to be an uncommon one. Since uncertain clinical diagnoses have been so frequently and generally made upon these cases, emphasis should be placed upon bacteriologic studies prior to death and after it. Many, but not all, stages in the development of *Blastomycoides histolytica*, as pointed out by Todd and Herrmann,⁷ were seen. We feel, as do Longmire and Goodwin,⁸ that the character of the lesions produced by this yeast is the result of an interrelation of factors, such as the virulence of the strain of organisms, the resistance of the host, and the hypersensitivity of the host. Further studies in cytology and on certain immunologic properties of this organism have been undertaken.

CLINICAL CHEMISTRY

CHEMICAL STUDIES IN DELIRIUM TREMENS*

CLARENCE COHN, M.D., PHILADELPHIA, PA.

TREATMENT of delirium tremens^{1, 2} has consisted mainly of procedures intended to dehydrate the patient. The post-mortem finding of cerebral edema in a large percentage of cases provided the basis for this type of therapy. This regimen has persisted in spite of the fact that many patients are obviously clinically dehydrated.

Attention was called to the unphysiologic nature of dehydration therapy in delirium tremens by Bowman and his co-workers,³ who showed that dehydrated excited alcoholic persons were benefited by oral or parenteral administration of hypertonic sodium chloride. In a later article,⁴ Bowman, Wortis, and Keiser advocated the use of large amounts of fluids, in addition to carbohydrates and sodium chloride, in an effort to readjust metabolism and blood chemistry. On the basis of unpublished data, they stated that the blood chloride and sodium were lowered and lactic acid was increased. The present study was undertaken in an effort to evaluate the physiologic and chemical basis for their recommendations.

MATERIAL AND METHODS

The criteria for the diagnosis of delirium tremens were: (1) History of alcoholism. (2) Visual and auditory hallucinations. (3) Delirium. (4) Excitement. (5) Disorientation. (6) Tremors of the hands and tongue. Patients admitted to the hospital with these findings were studied immediately on admission and after recovery, the latter study serving as control. Treatment varied but in general consisted of sodium chloride, fluids, thiamine, and nicotinic acid administered orally or parenterally. All patients in this series were males.

Blood sugar was determined by the method of Folin-Wu⁵; urea nitrogen by Karr's method⁶; serum proteins colorimetrically by means of the biuret reaction method of Kingsley⁷; and hemoglobin by means of the photoelectric photometer, according to Sheard, Sanford, and Osterberg.⁸ Serum chloride was measured by the method of Van Slyke, as modified by Wilson and Ball,⁹ total base by the electro dialysis method of Keys,¹⁰ and carbon dioxide combining power by the method of Van Slyke.¹¹ Spinal fluid proteins were measured by Looney and Walsh's turbidimetric method.¹² Available fluid was determined by the method of Crandall and Anderson¹³ utilizing sodium thiocyanate. Hematoerit values were obtained by use of the method described by Peters and Van Slyke.¹⁴

RESULTS

On admission serum chloride and carbon dioxide combining power were below normal in nearly all patients. Total base and available fluid determinations showed low or low normal values predominantly. Hemoglobin and serum protein concentrations, together with hematocrit values, were increased. The spinal fluid also showed changes. Chlorides were decreased and protein was increased. On recovery the concentrations of the substances studied returned to normal, with the occasional exception of the serum chloride. In four cases the recovery values for chloride were slightly below normal. The blood sugar and urea nitrogen showed no significant change.

All patients save one recovered; patient 8 died within twenty-four hours after admission as a result of lobar pneumonia. The pneumonia may have contributed to the factors causing the low serum chloride.

TABLE II

MEAN VALUES AND THEIR STANDARD ERRORS OF THE BLOOD CONSTITUENTS

In computing the value for protein, the values for patient 7 were omitted. "A" refers to admission values; "R" to values after recovery.

	HEMATOCRIT		HEMOGLOBIN (GM. %)		PROTEINS (GM. %)		AVAILABLE FLUID (L./M.)		CHLORIDES (MEQ./L.)		TOTAL BASE (MEQ./L.)		CO ₂ COMBINING POWER
	A	R	A	R	A	R	A	R	A	R	A	R	A
Mean	45.2	39.1	14.5	13.3	8.1	7.1	7.7	9.2	92.5	99.0	152	163	46
S. E.	±1.5	±1.8	±0.3	±0.5	±0.3	±0.3	±0.3	±0.3	±1.3	±1.6	±2.1	±2.4	

DISCUSSION

The ten patients on whom available fluid studies were performed on admission showed clinical evidence of dehydration. The available fluid values were at or below the accepted lower limits. In six of the ten, available fluid values were less than normal, and in the remainder low normal. After recovery the values were all within normal limits. Comparison of the mean values on admission and after recovery by the method described by Student using Fisher's¹⁴ table of *t* showed a significant difference. Crandall and Anderson,¹³ and Gregerson and Stewart,¹⁵ designate as available fluid, rather than extracellular fluid, the body water determined by the thiocyanate method. Normal values for available fluid are said to lie within the range of 22 to 29 per cent of the body weight, or between 8.7 and 9.2 liters per square meter of body surface area. Crandall and Anderson claim that the estimate of available fluid based on surface area is more accurate and less subject to variation than that based on body weight. This method was used.

Hemoconcentration existed in most, if not all, of the patients on admission. Hemoglobin, protein, and hematocrit values were high on admission when compared with the results of similar studies after recovery. Statistical analysis of the mean values on admission and after recovery showed the differences to be significant.

Total base and chloride determinations revealed hypochloremia and some evidence of base deficiency on admission. In only two of the fifteen patients

studied did chloride fall within normal limits. These two showed figures at the lower limits of normal of 98.0 meq. per liter. In four patients values between 96.0 and 98.0 meq. per liter were observed. All others showed chloride values below 94.0 meq. per liter. Comparison of the mean values of chloride on admission and after recovery indicated the differences to be highly significant. Total base on admission showed a marked departure from normal in only two patients. Recovery was accompanied by an increase in total base in two of the three patients for whom figures are available both before and after treatment. Gojcher and his co-workers¹⁶ noted an increase in serum potassium during chronic alcoholism. In combination with a lowered total base this finding would indicate that the serum sodium may be reduced more than the total base determination shows.

Himwich and co-workers,¹⁷ and Nicholson and Taylor,¹⁸ found an increase in blood lactic acid and a fall in carbon dioxide combining power and in blood pH in acute and chronic alcoholism. The fall in carbon dioxide combining power was confirmed in the present study. It is suggested that a contributory factor in the production of the acidosis in some patients is a deficiency in total base. However, the decrease in total base was less than the decrease in chloride and carbon dioxide combining power, with a resultant rise in undetermined anion. An increase in lactic acid or ketonic acids would provide a plausible explanation. Blood lactic acid, pyruvate, and acetoacetic acid determinations were performed in patient 13. Values only slightly above normal were found. The results, together with chloride, bicarbonate, and protein, left an apparent anion deficit of about 10 meq., suggesting the presence of other organic anions.

Examination of the spinal fluid revealed evidence of altered composition. Disregarding the cases with high blood sugars, about one-half of the remainder showed spinal fluid sugar above normal. A large proportion of the spinal fluid protein values were also above normal. The latter finding suggests either injury to the central nervous system or increased capillary permeability. Low spinal fluid chloride values can be explained by diminution in serum chloride. However, in two cases, in spite of a deficiency in serum chloride, spinal fluid chloride was maintained at normal concentration.

SUMMARY

1. Fifteen patients with delirium tremens were studied chemically on admission and after recovery.

2. Initially hemoconcentration, hypochloremia, lowered alkaline reserve, and some evidence of a decrease in total base were found. The volume of fluid available for solution of thiocyanate was decreased. Clinical and chemical evidence indicated the presence of dehydration.

3. Recovery was accompanied by a restoration of body fluids and electrolytes to normal composition.

4. Delirium tremens should be treated by methods which promote the restoration of fluid and salt.

5. Changes in the cerebrospinal fluid suggested the occurrence of injury to the central nervous system in certain patients.

I wish to express my appreciation to Dr. J. F. Stouffer and the Psychiatric Staff for permission to study their patients, and to Dr. J. G. Reinhold for suggestions and criticism.

THE EFFECT OF THE INTRAVENOUS ADMINISTRATION OF PHOSPHATE SOLUTION IN NORMAL RABBITS

IRVING GREENFIELD, M.D., BROOKLYN, N. Y.

SHELLING¹ emphasized the importance of phosphates in the successful treatment of animals exposed to the lead hazard and advocated its clinical use. Gray and Greenfield,² and later Gant,³ used the high phosphorus diets clinically in the treatment of patients with industrial plumbism. It was shown experimentally^{4, 5} that a high phosphate diet fed to rats during exposure, as well as during deleading, caused a sharp reduction in the amount of lead in the circulating blood. Kowaloff⁶ employed a high phosphorus regime in the treatment of a child with lead encephalopathy and showed a marked reduction in the circulating blood lead. In all the cited animal experiments the phosphate was administered orally. The oral administration of any form of therapy in patients with lead encephalopathy may not be practical because of vomiting. Calcium administered to these patients may aggravate the picture since it causes an increase in the circulating blood lead. Under these circumstances, the intravenous administration of a phosphate solution may be a life-saving procedure. Gant³ employed the alkaline dibasic sodium phosphate solution intravenously in the treatment of plumbism without untoward effects. Sobel⁷ and his co-workers have prepared a phosphate solution and used it experimentally in rabbits. They demonstrated that the intravenous administration of their phosphate solution produced a sharp reduction in the blood lead in many experimental animals, in some instances, within one hour after the injection.

The purpose of the following experiments was to observe the behavior of normal animals following the intravenous administration of the phosphate solution prepared by Sobel and his associates. Analyses of the blood and urine were made before and after the injection of the phosphate solution in order to observe the curves of the calcium and phosphorus levels in the blood and in the urine.

The solution used consisted of one part of sodium biphosphate and four parts of sodium phosphate dissolved in 45 parts of distilled water. This made a 10 per cent solution. It was filtered, sterilized, and set up in 10 c.c. ampoules. The pH of the mixture was approximately 7.4 so that no disturbance of the acid-base balance was to be expected following its intravenous administration.

Young chinchilla male rabbits weighing between 2 and 6 pounds were used in these experiments. The animals were anchored on an animal board and catheterized with a No. 6 French ureteral catheter. The marginal veins of both ears were then prepared with alcohol and xylol. After a control specimen of blood was taken from one ear, the phosphate solution was injected into the marginal vein of the opposite ear. The catheter was left in situ, and the urinary drainage was collected in individual containers at hourly intervals so that each

*From the Department of Medicine, the Jewish Hospital of Brooklyn, Brooklyn.
Received for publication, April 15, 1941.

specimen represented the kidney output for one hour. Samples of blood were obtained from the marginal ear veins at one-hour intervals. Calcium and phosphorus determinations of each of the urine and blood specimens were then made. The animals were kept under observation for four hours. During the experiment the rabbits were fed water by pipette. Food was withheld until after the completion of the experiment.

Experiment 4.—Weight of rabbit 2.95 kg.

The control specimens of urine and of blood were obtained. Five cubic centimeters of the phosphate solution were injected slowly. No abnormal behavior was noted. The specimen of urine obtained at the end of the first hour began to show traces of macroscopic blood. Samples of both urine and venous blood were collected at one-hour intervals for four hours following the completion of the injection.

TABLE I

SPECIMEN	SERUM		URINE		
	CALCIUM (MG./100 C.C.)	PHOSPHORUS (MG./100 C.C.)	VOL. (C.C.)	CALCIUM (MG./100 C.C.)	PHOSPHORUS (MG./100 C.C.)
Control	16.4	4.8	14	134.8	20.2
1st hour	9.4	6.8	15	108.0	98.5
2nd hour	14.4	5.8	14	20.8	48.5
3rd hour	12.9	5.4	9	94.8	33.6
4th hour	12.6	5.3	6	149.2	49.7

Six experiments in all were performed. Table I represents the typical responses noted. In order to determine whether the blood, which appeared following each injection of phosphate solution, was the result of a sudden precipitation of calcium phosphate crystals, two additional experiments were performed. In the first, the catheter was passed into the bladder and left in situ for four hours. No injection was given this animal. Blood appeared in the specimen obtained during the second hour. The catheter was then withdrawn sufficiently to remove the redundant portion of the catheter which, it was felt, was irritating the wall of the bladder. However, enough was left in the bladder to insure a free flow of urine. The subsequent specimens of urine were clear. In the second control rabbit the catheter was passed into the bladder, and after the sphincter reflex was exhausted and the catheter slipped into the bladder, it was withdrawn so that only enough remained in the bladder to insure a free flow of urine. None of the specimens obtained over the period of four hours contained blood. It was, therefore, felt that the blood noted in the specimens obtained in the previous experiments resulted from the irritation to the bladder wall caused by the catheter.

DISCUSSION

All the animals used survived the experiment and were alive for at least six months thereafter. The administration of the phosphate solution to the rabbits caused a sharp rise in the concentration of the serum phosphate as well as in the urine phosphate, and a decrease in the concentration of the serum calcium as well as in the urine calcium. During the second hour there was a secondary rise in the serum and urine calcium levels. The serum and urine calcium values did not return to the control levels within the period during which the animals were kept under observation. It was also noted that the serum and urine phosphate levels showed a secondary decrease, usually beginning within the second hour. Again the recovery fell short of the control level within the

period during which the rabbits were kept under observation. At no time did the observed calcium reach the level which is associated with low calcium tetany. Convulsive seizures were noted in two rabbits and fine tremors in one. These untoward results may have followed the formation of colloidal calcium phosphate, as demonstrated by McLean and Hindrichs⁸ in their experimental animals.

Gajato⁹ demonstrated that the toxicity of disodium phosphate was three times as great as the toxicity of monosodium phosphate. The pH of the phosphate solution used in the above experiments was 7.4 and closely approximated the pH of the blood. It appears from the experiments that a relatively large amount of this particular phosphate solution (0.463 Gm. per kilogram of body weight) may be administered intravenously. This phosphate mixture does not disturb the acid-base balance as does the disodium phosphate solution when administered intravenously, and, therefore, may be used with greater safety. There are many reports of the intravenous use of phosphate solution in the experimental literature. None have been found in which the phosphate solution was employed as a therapeutic procedure in plumbism. A report of these preliminary experiments was, therefore, considered indicated.

SUMMARY

1. A 10 per cent sodium phosphate solution at the pH of plasma was administered intravenously to rabbits.

2. The serum calcium level dropped and the serum phosphorus level rose following the intravenous administration of the phosphate solution.

3. The concentration of the urine calcium dropped and the urine phosphorus increased following the intravenous administration of the phosphate solution.

4. Convulsions were noted in two animals and tremors in one animal used in this experiment.

5. All rabbits were alive six months following the experiment and appeared to be normal.

I wish to thank Dr. S. M. Gordon, of The Endo Products Company, for his cooperation in preparing this solution suitable for intravenous use, and A. E. Sobel, of the Pediatric Research Laboratory of the Brooklyn Jewish Hospital, for his cooperation and many valuable suggestions.

LABORATORY METHODS

GENERAL

A NOTE ON THE PROBABILITY OF ERROR IN THE DIAGNOSIS OF RABIES BY MICROSCOPIC SEARCH FOR NEGRI BODIES*

S. R. DAMON, PH.D., MONTGOMERY, ALA., AND
T. F. SELLERS, M.D., ATLANTA, GA.

INTRODUCTION

THE microscopic diagnosis of rabies is accomplished by different workers in various ways; some prefer to look for Negri bodies in paraffin sections, some choose to make impressions, and others make smear preparations. Of the variety of methods the microscopic examination of smears or impressions made from Ammon's horn probably holds pride of place by virtue of its simplicity and the rapidity with which it can be performed. In any case, however, it is probable that a certain number of errors in diagnosis occur due to failure to demonstrate the characteristic intracytoplasmic inclusion bodies in the nerve cells.

Negri-Luzzani¹ reported the results of a study of 4,961 brain specimens by microscopic examination checked by animal inoculation; a total of 3,058 were positive by microscopic examination, but 6.7 per cent of the microscopically negative specimens were also found positive on animal inoculation. Koch and Jahn² reported a similar study of specimens received at the Robert Koch Institute during the period 1913 to 1928. Of a total of 8,366 specimens examined, 4,682 were positive, and of those negative microscopically, 11.8 per cent were positive when inoculated into animals. Leach³ has also reported that of 1,032 brain specimens examined, 12 per cent of those reported microscopically negative were positive on mouse inoculation. Commenting on the probability of such errors in diagnosis, Leach says, "the percentage of error will probably vary also with the prevalence of the disease in the geographic areas from which the material for diagnosis is obtained. In regions of high endemicity one might expect a high percentage of Negri negative specimens proving positive on animal inoculation."

When it is necessary to establish beyond question the diagnosis of rabies, animal inoculation is imperative. Until recently the guinea pig and rabbit have been considered the animals of choice for this purpose, but since the demonstration by Hoyt and Jungeblut⁴ that the intracerebral injection of rabies

*From the Alabama State Department of Public Health, Montgomery, Ala., and the Georgia State Department of Public Health, Atlanta, Ga.
Received for publication, January 17, 1941.

virus into white mice produced typical and constant infection, the white mouse has become increasingly popular as a test animal.

The only comparative study of the guinea pig and mouse inoculation methods we have found in the literature is that of Willett and Sulkin.⁵ These workers reported that of 25 specimens inoculated in parallel into mice and guinea pigs all were positive in the mice, while four were negative in the pigs. Perhaps this is too small a group to be statistically significant, but it does indicate that occasional positive specimens will be missed by guinea pig inoculation.

EXPERIMENTAL

With a view of testing particularly the accuracy of the foregoing statements as to errors in microscopic examinations, and of determining the actual percentage of error occurring in the routine diagnostic work in our laboratories, the results detailed here are reported. The sources of the material studied were the diagnostic laboratories of the State Department of Health of Alabama during the years 1937 to 1939, inclusive, and of the Georgia Department of Health during 1937.

In the routine procedure the animal heads were received in the laboratories, the brains were removed, and smears were made and examined in the usual fashion. Sellers^c stain was used to demonstrate the Negri bodies in both laboratories. After the smears had been prepared for direct microscopic examination, the remainder of the Ammon's horn was placed in pure glycerin and sent to the Rabies Laboratory for animal inoculation. Here white mice were injected intracerebrally with 0.03 c.c. of a 1:10 aqueous suspension of the hippocampus after trituration with alundum and centrifugation to throw down coarse particles. Table I gives an analysis of the findings on 1,320 specimens from Alabama, and on 754 specimens from Georgia.

TABLE I

NUMBER OF SPECIMENS AND RESULTS OF MICROSCOPIC EXAMINATION AND MOUSE INOCULATION IN ALABAMA FROM 1937 TO 1939 AND IN GEORGIA DURING 1937

LABORATORY	SPECIMENS EXAMINED	MICRO. - MOUSE -	MICRO. + MOUSE +	MICRO. - MOUSE +	MICRO. + MOUSE -	MICRO. - MOUSE +	MICRO. + MOUSE -	MICRO. - MOUSE +	MICRO. + MOUSE -
Alabama, 1937	527	353	111	51	5	2	4	1	0
Alabama, 1938	588	377	125	65	6	9	5	0	1
Alabama, 1939	205	167	22	11	0	12	12	0	1
Alabama, Total	1320	897	258	127	11	13	11	1	2
Georgia, 1937	754	445	231	62	6	5	0	4	1

Table I also gives the total number of specimens examined microscopically and subsequently inoculated into mice, together with a complete breakdown of the findings by both methods of diagnosis. Examination of the table brings out two particularly significant points: first, that in both Alabama and Georgia a significant number of specimens are reported as microscopically neg-

tive, which are actually found positive when inoculated into mice; second, that the number of specimens reported positive on the basis of microscopic examination, which are found to be actually negative when injected into mice, is insignificant.

Table II shows the number and per cent of specimens reported microscopically negative but found positive on mouse inoculation, together with the number and per cent of specimens reported microscopically positive but found mouse negative in the Alabama laboratories from 1937 to 1939, inclusive, and in the Georgia laboratories during 1937.

TABLE II

NUMBER AND PER CENT OF SPECIMENS MICROSCOPICALLY NEGATIVE FOUND MOUSE POSITIVE AND THE NUMBER AND PER CENT OF SPECIMENS MICROSCOPICALLY POSITIVE FOUND MOUSE NEGATIVE IN ALABAMA FROM 1937 TO 1939 AND IN GEORGIA DURING 1937

LABORATORY	YEAR	MICRO. NEGATIVE			MICRO. POSITIVE		
		TOTAL SPECIMENS	FOUND MOUSE POS.		TOTAL SPECIMENS	FOUND MOUSE NEG.	
			NUMBER	%		NUMBER	%
Alabama	1937	404	51	12.6	116	5	4.1
Alabama	1938	442	65	14.7	131	6	4.6
Alabama	1939	178	11	6.2	22	0	0.0
Alabama	1937-39	1024	127	12.4	269	11	4.1
(Total)							
Georgia	1937	507	62	12.2	237	6	2.5

From the figures given in Table II it will be noted that addition of the total microscopically negative specimens and microscopically positive specimens for each year gives a sum total somewhat different from the total number examined for that year, as given in Table I. The reason for this apparent discrepancy is that in Alabama in 1937, for example, there were actually only 404 specimens diagnosed as microscopically negative which when inoculated into mice gave a definite positive or negative result. In other words, the 7 specimens shown in Table I in which either the microscopic or mouse result was not clear-cut, i.e., was doubtful, have been eliminated.

DISCUSSION

It is probable that no single method of microscopic brain examination would yield 100 per cent correct results in the diagnosis of rabies. From the findings presented here it appears that in the laboratories of the Alabama State Department of Health, over a three-year period, slightly over 12 per cent of the specimens reported as negative, on the basis of microscopic examination of stained smears prepared from Ammon's horn, were in fact positive. During 1937 the microscopically negative mouse positive specimens constituted 12.6 per cent of the total diagnosed microscopically negative in Alabama, and 12.2 per cent of the total for the same year in Georgia.

It also appears that errors occur, but to a lesser extent, in the opposite direction. In Alabama, over the three-year period, just about 4 per cent of the specimens diagnosed as microscopically positive were negative when injected into mice. In 1937 in Alabama the number of microscopically positive specimens found negative on inoculation was 4.1 per cent of the total reported micro-

scopically positive, while in Georgia it was 2.5 per cent. However, these figures lose their apparent significance when the total number of specimens examined is considered.

An attempt at explanation of the above contradictions suggests speculation in several different directions: (1) the certainty with which Negri bodies are recognized by the examiners; (2) the failure to examine smear preparations carefully enough or to make them from the portion of the brain in which Negri bodies were present in sufficient numbers to be detected; (3) the presence in the dog population of strains of the virus which fail to elicit Negri body formation in the dog though capable of giving rise to the disease in mice; (4) the prevalence of distemper or other disease in the dog population which might give rise to inclusion bodies that could be mistaken for Negri bodies; (5) the failure to inject enough virus into the mice to cause rabies though Negri bodies were demonstrable in the original smears; (6) the viability of the virus when injected into mice due to its age or other factors.

CONCLUSIONS

1. In an area of high endemicity of rabies errors have been shown to occur in both directions in the microscopic diagnosis of the disease.

2. In Alabama it has been shown that over a three-year period an average of 12.4 per cent of the specimens reported as microscopically negative were actually positive, as shown by mouse inoculation.

3. In Alabama in 1937 the percentage of specimens microscopically negative and found positive on mouse injection was 12.6, while in Georgia the percentage was 12.2 for the same year.

4. In Alabama in 1937 the percentage of microscopically positive specimens found negative on mouse injection was 4.1, while in Georgia it was 2.5.

5. It is not possible to attribute definitely the discrepancies noted above to any one cause.

A METHOD FOR PREVENTING BLOOD CLOTTING IN CIRCULATION STUDIES*

R. H. K. FOSTER, PH.D., M.D., NUTLEY, N. J.

SINCE the introduction of methods for measuring blood pressure in acute experiments on laboratory animals, the prevention of coagulation has been an annoying problem. Various methods have been proposed to prevent coagulation, and several anticoagulants have been used, some of which, when introduced into the circulation, are apt to produce toxic manifestations and alter the experimental results. MacCracken and Werness¹ proposed a method in which a portion of the carotid artery was isolated and sectioned, and the proximal end was passed through and everted over the end of a short glass tube and tied in place. It was then placed in a small glass chamber filled with sodium sulfate solution. A side arm of this chamber was connected to a mercury manometer. This device avoided the use of a cannula but was somewhat troublesome to set up, and the authors admitted that clots occasionally formed.

Trendelenburg² proposed a method in which the anticoagulant solution (one-sixth molar sodium bicarbonate) was introduced into the cannula in a slow stream. The rate of flow was regulated by dropping mercury into a closed vessel containing the anticoagulant solution and connected to the cannula. This method, while satisfactory in some respects, is open to the objection that the anticoagulant solution is continuously introduced directly into the animal.

In using a mercury manometer marked changes in blood pressure result either in a sudden flow of the anticoagulant solution into the animal or in a complete filling of the cannula with unprotected blood. In the former case the anticoagulant may affect the experimental results, and in the latter case a clot may form in the cannula. Even the pressure changes occurring with the heart-beat continually wash a considerable amount of blood in and out of the cannula, rapidly dissipating the anticoagulant. The use of a membrane manometer† greatly reduces the volume of this ebb and flow.

In an attempt to improve the technique of preventing clotting, a new type of arterial cannula, to be used in conjunction with heparin or other anticoagulants, has been devised. The cannula (Fig. 1), essentially an ordinary three-way wash-out cannula, has a fourth short outlet with a slightly flared rim and is placed at right angles to the other three outlets. A rubber serum vial stopper‡ (A) is inserted into the fourth outlet tube, and the thin upper sleeve is inverted over the flared rim of the tube. This securely anchors the stopper. The tip of the cannula is introduced into the artery in the usual manner and is filled with

Received for publication, November 2, 1940.

†The Harvard Apparatus Co., Dover, Mass.

‡No. 1A sleeve stopper, obtainable from the West Company, 1117 Shackamaxon Street, Philadelphia.

normal saline under enough force to wash out all air bubbles through the side arm. The side wash-out arm is closed and the connection to the manometer is made. Pressure in the system is raised to about 150 mm. of mercury. The artery clamp is removed and 0.6 mg. of heparin* in 0.15 ml. of solution is introduced immediately through the rubber cap by means of a hypodermic needle ($\frac{1}{2}$ inch, No. 25). In blood pressure studies on cats this dose of heparin is usually repeated one to three times during an experiment. Although the solution in the cannula gradually becomes diluted, even with the membrane manometer, the dilution occurs much more slowly than with a mercury manometer.

Figs. 1 and 2.

Any other anticoagulant can be used, of course, but heparin is preferable, since it is the only physiologically normal anticoagulant known and available. Complete heparinization of an animal requires considerably more heparin than three or four of the above doses. According to Reinert and Winterstein,³ the clotting time of rabbit's blood is longer than one hour, three hours after the intravenous injection of 3,000 a.c.u. per kilogram, or two hours after the injection of 1,500 a.c.u. per kilogram. From this it is estimated that a 3 kg. animal would require fifteen to thirty times as much heparin for general heparinization lasting three hours as for local use by introduction directly into the arterial cannula.

*Heparin was employed in the form of Liquaemin 'Roche' containing 2,000 Roche "anti-coagulant units," or 4 mg. per milliliter.

A venous cannula* (Fig. 2) was designed to facilitate intravenous administrations, particularly when a great many injections have to be made during the course of an experiment. The side arm of the cannula is connected to a reservoir of physiologic saline (a 50 c.c. burette is most convenient). The rubber vial cap† (B) is slipped over the end of the tube. Injections are made, using a syringe and No. 22 needle, preferably long enough to reach just to the constricted tip of the cannula. The solution is injected and immediately washed in with 1 or 2 c.c. of saline. The rubber cap B used with the venous cannula is not satisfactory for the arterial cannula because of the much higher arterial tension, but under venous pressure the cap may be punctured many times without the occurrence of leakage.

SUMMARY

The prevention of clotting during a blood pressure experiment requires a suitable anticoagulant, preferably heparin; a membrane manometer to reduce the volume of the ebb and flow of the blood; and a special arterial cannula herein described for introducing small volumes of the anticoagulant solution.

THE LAUGHLEN TEST FOR SYPHILIS*

WILLIAM B. DUBLIN, M.D., AND MARTIN ELTRICH, M.T.
FORT STELLACOOM, WASH.

NUMEROUS reports have been made on the degree of reliability of the Laughlen test. Some have been favorable; others have been adverse.

We wish to report the results of 1,008 consecutive tests on inactivated serum made at the Western State Hospital in comparison with the Kolmer-Wassermann and Kahn tests.

Of the 1,008 specimens, 112 gave reactions of some degree with one or more of the three tests. Most of these patients had syphilis of the central nervous system. Results of 336 tests in these 112 cases were classified as "satisfactory," "questionable," or "unsatisfactory." In the "satisfactory" group all three tests gave positive reactions. Usually, approximately the same strength of reaction occurred with the three tests; however, in many instances a moderate variation occurred. In the "questionable" group a weak reaction occurred with one

*From the Division of Pathology, Western State Hospital, Fort Steilacoom.
Received for publication, December 13, 1940.

test in the absence of reaction with the other two tests, or there was no reaction with one test in the presence of weak reactions with the other two tests. In the "unsatisfactory" group a strongly positive reaction occurred with one test in the absence of a reaction with the other two tests, or vice versa. It is our purpose not to judge whether, in such instances, the minority or the majority was correct, but simply to compare the tests with each other.

The Kolmer test gave 98 "satisfactory," 8 "questionable," and 6 "unsatisfactory" results. The Kahn test gave 102 "satisfactory," 8 "questionable," and 2 "unsatisfactory" reactions; the Laughlen test gave 106 "satisfactory," 3 "questionable," and 3 "unsatisfactory" results. In two cases in which the Kolmer test was strongly positive in the absence of a reaction to the other two tests, the patients were known to have syphilis; treatment had been instituted. Some of the "unsatisfactory" Kolmer reactions may have been correct, although in the minority.

Judged on the afore-mentioned basis, the Kolmer test showed 99 per cent sensitivity and 91 per cent specificity; the Kahn test showed 98 per cent sensitivity and 93 per cent specificity; the Laughlen test showed 95.5 per cent sensitivity and 99 per cent specificity. "Questionable" reactions were included in computing sensitivity and specificity.

The greater sensitivity of the Kahn test indicates its greater reliability than the Laughlen test as an emergency test for blood donors. If one uses inactivated serum, the Kahn test requires little more time than the Laughlen test.

The Laughlen test appears to be worthy of use with the Kolmer-Wassermann and Kahn tests in providing, without burdening the laboratory unduly, a routine three-test repertoire.

A PRESSURE SEITZ FILTER FOR LABORATORY USE*

EDWIN E. HAYS, M.S., CHICAGO, ILL.

THERE appears to be a need for a small laboratory sterilizing filter capable of handling small volumes of solutions to render them sterile for injection purposes. The usual laboratory filter is dependent upon suction to draw the solution through it and is, therefore, limited in its use for volatile and viscous solutions. In addition, the suction type actually requires some manipulation to seal the solution into a contamination- and evaporation-proof container under sterile conditions. Many existing filters have a tendency to retain comparatively large amounts of solution and, for this reason, it becomes impractical to use such a filter with small volumes. The device described here is designed to eliminate these difficulties and to make it possible to place the sterilized solution directly into a sterile vial which automatically seals itself against contaminants and evaporation.

Pressure is used to force the solution to be sterilized through a Seitz paper mat. The solution is forced directly into a sterile, rubber-closed vial, thereby eliminating all possibilities of contamination.

The apparatus is made of chromium plated brass and is constructed to withstand a pressure of approximately 150 pounds per square inch. Fig. 1 shows the constructional details. A standard Seitz mat is cut to the desired size and placed over the removable perforated disk *C*. The lower end of the apparatus is tapered to fit a standard hypodermic needle. The two main parts are knurled at *A* and *B* to facilitate the tightening of the Seitz mat. The top plug *D* is fitted with a lead gasket to prevent leakage.

METHOD

The apparatus is assembled, placed in a metal container, and autoclaved for fifteen minutes at 15 pounds' pressure. A vial of an appropriate size to receive the sample and with two hypodermic needles, plugged with cotton and penetrating its rubber cap (see Fig. 2), is autoclaved at the same time. After cooling, one of the cotton plugs is removed, and after flaming the needle, it is attached to the apparatus, and the device is fastened into a support. Since no bacteria can enter the vial, the apparatus may be kept in this condition as long as desired.

Pressure tubing is attached to the air inlet. A high pressure tank of nitrogen or an ordinary compressed air jet may be used to supply the required pressure.

*From the Department of Biochemistry, the University of Chicago.
Received for publication, January 14, 1941.

The sample (1.5 to 10 c.c.) is placed into the apparatus by removing cap *D*. The cap is tightened by means of a rod inserted through its top. Pressure is applied slowly at first, and finally to a point just sufficient to force the liquid into the vial. When the desired sample is obtained, the pressure is released and the needles are removed from the vial.

Fig. 1.

The apparatus was tested using a culture of *Bacterium prodigiosum* in nutrient broth. The culture was passed through the filter, and the filter and part of the original culture were plated out. Similar tests were performed using tissue extracts and blood serum. All tests have shown the complete absence of bacteria in solutions passed through the filter.

The apparatus may be secured from the machine shop, of the Department of Biochemistry, the University of Chicago.

MESTER'S TEST IN RHEUMATOID ARTHRITIS AND SPONDYLITIS RHIZOMELIQUE*

M. E. GREEN, M.D., AND R. H. FREYBERG, M.D.
ANN ARBOR, MICH.

IN 1937 Mester¹ reported results of a salicylic acid skin test in patients with rheumatic and nonrheumatic conditions and concluded that it was a specific diagnostic test for "rheumatic diseases." This conclusion was confirmed in similar studies by Lenocho,² and later by Braghin.³ The latter author reported that the test was positive in all 45 patients who were suffering from rheumatic diseases, including "acute, subacute, and chronic rheumatic polyarthritides, rheumatic ankylopoietic spondylarthritides, rheumatic ischialgia, rheumatic fever with cardiac complications, and chronic rheumatic iridocyclitis." The test was negative in patients with "non-rheumatic" joint diseases, which included gonococcal arthritis, gout, tuberculosis, and syphilis.

If the test were sensitive and specific, as stated by the above-mentioned authors, it would be of great value in the diagnosis of early spondylitis rhizomelique and of atypical atrophic arthritis, and in the exclusion of gout, gonococcal arthritis, and degenerative disease of joints. Since it is sometimes difficult to differentiate these forms of rheumatism, we desired to determine the dependability of Mester's test.

Employing the technique of Braghin,³ the test was performed in 20 patients with rheumatic disease, 16 of whom had characteristic rheumatoid arthritis, and 4 had spondylitis rhizomelique, and in a control group of 10 nonrheumatic patients. Blood was withdrawn from the middle finger of the right hand of the fasting patient before, and again thirty and sixty minutes after, the administration of two intracutaneous injections of 0.2 c.c. of a sterile 0.1 per cent aqueous solution of salicylic acid, and the number of leucocytes in each blood specimen was determined. The injections were made on the volar surface of the right forearm at a distance of about 5 cm. from each other. These injections were usually followed by pain and burning of short duration, and by the formation, at the sites of injection, of erythematous wheals which disappeared in a few hours. A positive test consists of a transient diminution of the leucocytes, usually within the first thirty minutes, and less frequently within the second thirty minutes after the injection of the salicylic acid solution. A decrease in the leucocyte count of 20 per cent or more was considered a positive test; a rise in the leucocyte count, no change or fall of less than 20 per cent, were considered as negative.

*From the Rackham Arthritis Research Unit and the Department of Internal Medicine, the Medical School of the University of Michigan, Ann Arbor.

The Rackham Arthritis Research Unit is supported by the Horace H. Rackham School of Graduate Studies, University of Michigan.

Received for publication, January 17, 1941.

The test gave negative results in all 10 patients with nonrheumatic disease. In the group of 20 with rheumatoid arthritis or spondylitis rhizomelique, a positive test was obtained in only 5 instances (Table I).

RESULTS OF MESTER'S TEST IN PATIENTS WITH RHEUMATOID ARTHRITIS AND SPONDYLITIS RHIZOMELIQUE

DIAGNOSIS	LEUCOCYTE COUNT (CELLS PER C.M.M.)			
	BEFORE INJECTION	30 MIN. AFTER INJECTION	60 MIN. AFTER INJECTION	RESULT
Rheumatoid arthritis	10,600	6,100	5,200	Positive
Rheumatoid arthritis	8,850	8,950	9,000	Negative
Rheumatoid arthritis	6,400	6,200	6,200	Negative
Rheumatoid arthritis	7,250	8,100	8,000	Negative
Rheumatoid arthritis	8,800	9,000	8,700	Negative
Rheumatoid arthritis	7,000	7,200	6,900	Negative
Rheumatoid arthritis	7,950	7,700	7,400	Negative
Rheumatoid arthritis	4,100	4,200	4,050	Negative
Rheumatoid arthritis	8,850	5,100	5,400	Positive
Rheumatoid arthritis	4,000	4,200	4,300	Negative
Rheumatoid arthritis	8,100	6,900	8,200	Negative
Rheumatoid arthritis	10,450	10,600	10,400	Negative
Rheumatoid arthritis	6,750	6,200	6,400	Negative
Rheumatoid arthritis	7,200	6,400	6,000	Negative
Rheumatoid arthritis	8,800	8,450	8,400	Negative
Rheumatoid arthritis	8,300	6,150	8,450	Positive
Spondylitis rhizomelique	9,200	9,000	6,100	Positive
Spondylitis rhizomelique	4,550	4,100	4,350	Negative
Spondylitis rhizomelique	11,300	8,400	8,800	Positive
Spondylitis rhizomelique	4,600	4,600	4,450	Negative

Although the test was negative in our control cases, it was also negative in the majority of patients with typical arthritis; in this our results do not agree with those reported by others.¹⁻³ Braghin, for instance, stated the test was positive in *all* of 45 patients suffering from "rheumatic disease." In our group of 20 patients the test was positive in only 25 per cent. Because of these disappointing results, we did not attempt to determine the "specificity" of the test in differentiating certain rheumatic diseases from gout, gonococcal, and tuberculous arthritis, for even if it were always negative in the latter group, the test would be very unreliable, due to the fact that we found it negative in the majority of patients with characteristic rheumatoid arthritis.

CONCLUSION

Mester's test was found to be grossly unreliable as an aid in the diagnosis of characteristic rheumatoid arthritis and spondylitis rhizomelique, which accordingly makes it of little value in differentiating certain forms of rheumatic disease.

DETERIORATION OF CORN GERM STEROL*

ANNE C. KIMBALL, PH.D., MINNEAPOLIS, MINN.

IN 1932 Eagle¹ introduced a new sterol, corn germ sterol, for use in fortifying the antigen used in his Eagle flocculation test for syphilis, in addition to the more widely used cholesterol. The major advantage of this sterol as an antigen sensitizer is that the antigen emulsion for use in the test is more stable if corn germ sterol is used than are emulsions made with antigens sensitized with cholesterol alone. In a later modification of the flocculation test² the use of both sterols was again recommended.

Recently four preparations of Eagle antigen made in our laboratories from three different lot numbers of Difco beef heart have been found unsatisfactory for use when fortified with old corn germ sterol and fresh cholesterol. These unsatisfactory antigens when tested with sera, which gave a negative reaction to three other nationally recognized tests, show a markedly granular appearance and do not give the "silky swirl" on shaking that is so characteristic in the negative Eagle test. When read microscopically, the granularity observed would justify a reading of doubtful. Strongly positive sera gave characteristic reactions with these antigens, but weak reactions are difficult, if not impossible, to read accurately.

These four unsatisfactory antigens were prepared, one in March, 1940, two in July, 1940, from two different lots of beef heart, and one in August, 1940, using the same beef heart as was used for one of the July preparations. Judging by the degree of granularity observed in tests with negative sera, the deterioration had progressed very rapidly during these five months. This rapidly progressive deterioration is suggestive of an autocatalytic oxidation.

Separate aliquots of three of the four Eagle antigens have been fortified with the same fresh cholesterol and fresh corn germ sterol. With all three of these antigens the negative sera tested have given a characteristic appearance.

The old corn germ sterol was purchased in December, 1932. Difco Laboratories has informed our laboratories that this sterol was made in 1931. Since its purchase this sterol has been kept at room temperature in the brown glass bottle, stoppered with the paper covered cork as received. At this time the old sterol has a yellow tinge and the fresh sterol is white. This color change is also suggestive of a rancidity oxidation. The melting point of this old sterol has been checked at the Difco Laboratories, and it is found to be about 96° C. over a range of approximately 5° C., while in 1931 when the material was prepared the melting point was sharp at 138° C.³ Eagle antigen prepared in May, 1938, in which this old sterol was used, is still entirely satisfactory.

*From the Division of Preventable Diseases, Minnesota Department of Health.
Received for publication, January 21, 1941.

From these observations it can be concluded that corn germ sterol deteriorates with age, undergoing an atmospheric oxidation, and is then unsatisfactory for use in Eagle flocculation antigens. It is suggested that this deterioration be guarded against in laboratories in which the Eagle test is used. It seems advisable to keep this sterol in a refrigerator, since this would tend to slow up oxidation. The one sample of sterol here studied was satisfactory for about six years. Other samples might vary in speed of deterioration, and varying laboratory conditions might markedly affect the rate of this chemical change. It, therefore, seems inadvisable to use corn germ sterol for an extended period of time.

FACTORS INFLUENCING THE DEMONSTRATION OF TUBERCLE BACILLI BY CONCENTRATION METHODS*

LENORE ROBINSON, M.S., AND W. D. STOVALL, M.D.
MADISON, WIS.

FOR the detection of small numbers of tubercle bacilli in sputum or gastric aspirations the most widely used methods have been culture or animal inoculation. Each of these methods is quite time-consuming, both from the standpoint of the technique employed in the laboratory and the time interval before the clinician receives his report. In addition to this, animal inoculation, which is the more dependable test, is very expensive when used on a large scale. With the increasing use of the laboratory for determining the infectivity of early and convalescent cases of tuberculosis, much study has been expended to determine a method of direct examination which will suffice in a large proportion of such cases and will thus reduce the number of guinea pigs required. A number of methods for concentrating sputum and gastric aspiration have been developed with varying claims for their usefulness. Some investigators have regarded their concentration methods to be superior to guinea pig inoculation. However, it must be remembered that the pathogenicity of an acid-fast organism cannot be determined by the morphology and staining reaction of the organism, and in doubtful cases the guinea pig inoculation is still the final test.

The concentration method depends on (1) the digestion of the mucus and cellular elements in the specimen, and (2) the collection of the organism for staining. The wide variation in the character of the sputum or gastric aspirations leads to difficulty in selecting a digester which will work equally well with all types of specimen. In evaluating the various methods of concentration it

*From the University of Wisconsin, State Laboratory of Hygiene, Madison.
Received for publication, January 23, 1941.

is necessary to balance the results against the time and expense of procedures. The ideal method to be applied to large numbers of examinations should be simple and should produce a material which is entirely satisfactory for smearing and staining. The concentration should be sufficiently effective so that the material from a large amount of the original specimen can be examined.

The methods for concentrating sputa which are most widely used are the antiformin method of Uhlenhuth and Xylander⁷ and the sodium hydroxide method of Petroff.⁴ These methods consist of the digesting of the specimen by alkali, centrifuging out the organisms, and making stained smears. To facilitate the separation of the organisms from the digested specimen, flotation with ligroine or other hydrocarbons, as developed by Kinyoun,³ or precipitation with alum or ferric chloride (Hanks, Clark, and Feldman²) have been used. Volatile hydrocarbons were used by Andrus and MacMahon¹ to aid in sedimenting the organisms. Various modifications of these methods have been reported. A number of other types of digesters have more recently been advocated by various workers who attribute to them definite advantages over normal sodium hydroxide. Among these are such vegetable ferments as caroid (Sullivan and Sears⁶), animal ferments as trypsin (Vogt, Zapposodi, and Long⁵), and organic solvents as "tergitol, penetrant 08" (Petroff and Schain⁵). Each of these is more expensive and less available, and their use is more time-consuming than treatment with normal sodium hydroxide. Therefore it would seem that there should be quite an increase in positive results to make them superior to sodium hydroxide for routine use. The same may be said for the various methods for collecting organisms from the digested specimens.

For these reasons, we have made a study of these various methods in comparison with sodium hydroxide. Our chief concern was to find the best method for handling gastric aspirations, but since sputa are more readily available in quantity, the first part of our study was made using sputa, especially mucoid or mucopurulent types, and the methods giving best results were later applied to gastric specimens.

EXPERIMENTAL

The two stages in the concentration of a sputum are: (1) the digestion of mucus and cellular elements, (2) the collection of the organisms for staining.

Digestion.—The technique which we used with sodium hydroxide, and with which we compared other methods, was as follows: To a measured quantity of sputum was added an equal quantity of normal sodium hydroxide and this was shaken well. The mixture was incubated for thirty minutes at 37° C. with occasional shaking. At the end of the incubation period the specimen was shaken well, neutralized to just alkaline to bromthymol blue, and centrifuged for thirty minutes at about 2,000 r.p.m.

Sodium hydroxide has the disadvantage of being injurious to the organisms if left too long in contact with them and may destroy their acid-fast character. It also appears to cause some clumping of the organisms so that distribution on the smear may be irregular. These, and the presence of crystals on the smears, were the disadvantages we tried to overcome.

1. *Alkali.* Other alkalies were tried—calcium hydroxide and ammonium hydroxide—using the same technique. A saturated calcium hydroxide solution

required much longer to be effective, and the results then were not equal to those with normal sodium hydroxide. Normal ammonium hydroxide appeared to liquefy the specimen almost as rapidly as normal sodium hydroxide, but it was in no way superior.

2. *Acids.* Acid digestion with 6 per cent sulfuric acid was tried, using the same technique as above, neutralized with sodium hydroxide and with ammonium hydroxide. This was fairly satisfactory for digesting mucus, although not so rapid in action as normal sodium hydroxide. However, pus cells were left intact, and in mucopurulent specimens the sediment after centrifuging was quite heavy. The smears after this treatment show a nice distribution of the organisms, but sometimes they show extraneous material which is difficult to decolorize.

3. *Animal ferments.* Trypsin is an animal ferment which acts on mucus. However, its action is not sufficiently vigorous to take care of all types of specimens and frequently there is a large volume of sediment or quite a viscous digest.

4. *Vegetable ferments.* Caroid, while it does not digest pus actively, is more satisfactory than trypsin. It appears to be more active in an alkaline medium, hence the addition of equal quantities of a 0.1 to 0.2 per cent sodium hydroxide solution to a 5 or 2 per cent caroid solution is more effective than either would be alone. Occasionally caroid smears are difficult to decolorize, but generally the smears have an even background and good distribution of well-stained organisms. Caroid is less destructive to the organisms than sodium hydroxide, and the digest may be allowed to stand several hours without apparent effect on the staining of the acid-fast organisms.

5. *Organic solvents.* "Tergitol, penetrant OS" in solution with sodium hydroxide, as recommended by Petroff, is an active solvent, liquefying sputum in about the same length of time as normal sodium hydroxide. It appears to be more destructive to the organisms, since fewer organisms were found in the smears from the same specimens after this method of digestion than after digestion with normal sodium hydroxide.

From the study made it appears that the most satisfactory digesters are normal sodium hydroxide and caroid (2 to 5 per cent caroid with 0.2 to 0.1 per cent sodium hydroxide). Normal sodium hydroxide has the disadvantage of being injurious to the organisms, and if left too long in contact will destroy the acid-fast properties. However, there is a wide margin of safety between the time needed for satisfactory liquefaction of the specimen and the time at which injury to the organism is evident. Thirty minutes is sufficient time for liquefaction of all types of specimens except the very tenacious or very purulent. When these types of specimens are mixed with one or two volumes of distilled water, shaken well, and then mixed with an equal volume of normal sodium hydroxide, they, also, are generally liquid in thirty minutes. Reduction in the number of organisms demonstrable by smear is not noticed until more than one hour exposure to normal sodium hydroxide.

Caroid is less destructive to the organisms than sodium hydroxide, and the sediment generally makes very nice smears with well-stained organisms. However, since it does not digest the cellular elements there is frequently a heavy sediment, and sometimes the smears are difficult to decolorize.

Collection of Organisms.—After the specimen is thoroughly liquefied, the organisms are to be collected for staining. In the above studies this was done by centrifugation for thirty minutes at about 2,000 r.p.m. In addition to this, various methods of facilitating sedimentation were compared and a study made of the factors which might influence the separation of the organisms from the digest.

1. To study the effect of specific gravity, aliquots of the digest were centrifuged without dilution, diluted with two volumes of distilled H_2O , and with two volumes of 95 per cent alcohol, respectively. These were centrifuged as above. A comparison of diluted specimens with undiluted specimens gave the following results: Of 20 specimens digested with normal sodium hydroxide, 9 showed more organisms without dilution with water than with dilution, 8 showed more organisms when diluted, and 3 were approximately equal. No definite relationship between type of specimen and the effect of dilution could be discovered. Of 10 specimens diluted with alcohol, 7 showed fewer organisms when diluted, and 3 showed about equal numbers. Since 95 per cent alcohol frequently gives a heavy, rather tough sediment, 50 to 75 per cent alcohol was used instead, or 95 per cent in quantities just short of the amount which would produce heavy precipitation. No definite improvement in number of organisms was obtained.

Of 20 specimens digested with caroid (1, 2, or 5 per cent), 12 showed fewer organisms when diluted with two volumes of distilled water, 6 showed more organisms, and 2 were about equal. Of these same specimens 13 showed fewer organisms when diluted with two volumes of alcohol, 6 showed more, and one was about equal. The above results would indicate that the lowering of the specific gravity by dilution with distilled water or alcohol has no great advantage if the specimen is thoroughly liquefied by the digesting process. However, with specimens which give a viscous digest there appears to be an advantage in dilution. It is more satisfactory to add distilled water (equal volume or more, depending on the degree of viscosity) to the specimen and mix it well before the digester is added. This gives a more satisfactory liquefaction with a lower concentration of the digester; for example, 10 c.c. sputum + 10 c.c. distilled water + 20 c.c. normal sodium hydroxide = a concentration of 2 per cent sodium hydroxide. This gives a more satisfactory digest than 10 c.c. sputum + 20 c.c. normal sodium hydroxide which gives a slightly higher concentration of sodium hydroxide.

2. *Chemical flocculation.* The use of alum, ferric chloride, or sodium carbonate to collect the organisms by flocculation of the proteins was of no definite advantage in our hands. The heavy precipitate from a given quantity of digest greatly reduces the amount of the original specimen which can be used for the examination so that any increase in the proportion of organisms precipitated out is balanced by the smaller quantity examined.

3. *Volatile hydrocarbons.* Following the work of Andrus and MacMahon, specimens, after digestion and neutralization, were shaken with a few drops of chloroform (about 1 drop per cubic centimeter of digest) and centrifuged. The chloroform collects in the bottom of the tube, and the sediment containing the tubercle bacilli forms a layer just above it. This sediment forms a satis-

factory material for staining, giving a good distribution of well-stained organisms. Although the results, again, were not entirely consistent, there appeared to be an advantage in the use of chloroform with digested sputa.

Of 36 specimens digested with sodium hydroxide, 22 showed more organisms when treated with chloroform, 10 showed more organisms untreated, and 4 showed about equal numbers. Of 14 specimens digested with caroid, 7 showed more organisms treated with chloroform, 5 showed fewer, and two showed about equal numbers.

STUDY OF FACTORS INFLUENCING SEDIMENTATION OF TUBERCLE BACILLI

1. *Surface tension depressors.* On the possibility that a lowering of the surface tension of the suspending medium might allow the organisms to be more readily centrifuged, various materials were added to the digested specimen for the purpose of lowering surface tension. These included a stock soap solution, aerosol (0.1 per cent), sodium glycocholate (5 per cent), urea (5 and 20 per cent), and dreft (0.1 and 1 per cent). The results, as with attempts to lower specific gravity, were so varied and inconsistent that no definite conclusions could be drawn. A study of surface tension values was made together with pH values as given below.

2. *Variations in the acids used for neutralizing and a study of pH values.* Sodium hydroxide digests of sputa were used entirely for this part of the work. In the beginning hydrochloric acid was used for neutralization, but since this gave rather heavy salt precipitates the effects of neutralization with sulfuric acid, oxalic acid, and acetic acid were studied. Comparisons were also made of the number of positive slides and the number of organisms per slide found with the sediment from each. The specimens neutralized with acetic acid gave somewhat better results in the number of organisms found and also gave a smear which was easier to examine, showing less extraneous acid-fast material. In the later studies the sodium hydroxide digests were neutralized with 25 per cent acetic acid.

The pH reading and surface tension readings were made on a number of specimens and compared with the count of bacilli on stained smears to determine if there might be a direct relationship between these values and the separation of organisms from the digest. Each specimen was divided into equal parts, and acid was added to secure various degrees of alkalinity or acidity. Other portions of the specimen were treated with alcohol, tergitol, soap, and aerosol to vary the surface tension. Table I shows the pH and surface tension readings of the preparation of each specimen which showed the largest number of bacilli by smear. The smears were made by spreading the material evenly between two slides, and examination consisted of careful observation of three lines across the slide. In some cases more than one preparation gave approximately equal numbers of organisms. In such cases more than one preparation from a specimen is included in the table.

It is noted that there is a wide range of pH and surface tension values through which sedimentation of the organisms goes on equally well. The optimum pH seems to lie between 9 and 11, while the optimum surface tension is between 63 and 73, which is approximately the reading of the neutralized

sodium hydroxide digest without any further treatment. A caroid digest of the average sputum is also in this range. These surface tension readings were made on the Du Nouy apparatus and are based on a reading for distilled water of 108. pH readings were made on the Coleman pH electrometer.

The character of the sputa from patients with tuberculosis or suspected tuberculosis varies to such a degree that we have been unable to lay down a method of examination which is definitely superior for all types of sputum.

TABLE I

SPECIMEN NUMBER	NUMBER OF ORGANISMS	pH	SURFACE TENSION
28	88	12.2	61
29	8	10.0	
	8	11.8	
30	1	5.7	
	1	8.1	
31	1	8.8	63
	1	8.8	67.5
32	4.6 (average per field)	10.15	73
	4.6 (average per field)	9.0	70
	4.3 (average per field)	5.3	61
33	2	9.8	60.5
	2	10.75	75
34	6	11.0	52
35	4	9.0	67
	4	11.1	67
36	156	8.9	73
37	3	9.15	67

The inconsistency of results would suggest that the method of handling is less important than the uneven distribution of organisms in the original specimen. To overcome this we believe that a large quantity of the specimen should be digested. The entire quantity should be digested rather than 5 to 10 c.c., as has been recommended for sputa, or rather than the sediment from centrifuged gastric aspiration. After thorough liquefaction long centrifugation is necessary to sediment the bacilli. The addition of chloroform appears to be an aid in sedimentation, without increasing the amount of sediment. On the other hand, chemical flocculation increases the amount of sediment to such a degree that the sediment from a smaller proportion of sputum is used for the smears and the chance of finding bacilli in the smears is not increased.

Application of Gastric Aspirations.—A total of 287 gastric specimens, which were negative by direct centrifugation were examined by concentration methods. The quantity used varied from 10 to 40 c.c. At first these were digested with equal quantities of normal sodium hydroxide, but it was discovered that 2 per cent sodium hydroxide was satisfactory for these as the proportion of mucus is generally much lower than in sputa. They were digested for thirty minutes at 37° C., neutralized to approximately pH 9 with 25 per cent acetic acid, and centrifuged for thirty minutes at about 2,000 r.p.m. Of the 287, 34 per cent were positive by one method. In 64 specimens an equal portion was shaken with chloroform before centrifugation. Of these 64 specimens examined both with and without chloroform, 25 were positive with chloroform and 23 without chloroform. The advantage of chloroform was less marked here

than in sputa, perhaps because the gastric specimen is more completely liquefied and has a lower specific gravity than the sputum. The small increase in positive results does not appear to warrant the extra handling.

Routine Use in the Laboratory.—For a period of nine months we have been using this method of concentration on routine gastric aspirations and sputum specimens in this laboratory. Letters were sent to the various sanatoriums in the state requesting that, whenever possible, specimens which would ordinarily be sent to this laboratory for guinea pig inoculation should be sent rather for concentration. If this proved negative a second specimen should be sent for guinea pig inoculation. We did not make direct smears as the sanatoriums generally send in only specimens from patients who have been previously negative by smear.

Gastric aspirations were received in the laboratory as either single or pooled specimens (specimens taken on three successive days and pooled) in quantities of from 10 to 100 c.c. The entire quantity was shaken with an equal quantity of 2 per cent sodium hydroxide and incubated at 37° C. for thirty minutes. These were then neutralized with 25 per cent acetic acid to just alkaline to bromthymol blue (pH 8 to 9), and centrifuged at about 2,000 r.p.m. for thirty minutes. In most cases the entire quantity of sediment could be smeared between two slides without making the smears too heavy for examination. These smears were stained by the Ziehl-Neelsen method.

Sputa, unless rather tenacious, were handled in the same way. Those with a large proportion of mucus or pus were first shaken with an equal quantity of distilled water and then with an equal quantity of 2 per cent sodium hydroxide, or if necessary normal sodium hydroxide.

During this period, 807 gastric aspirations and 290 sputa, or a total of 1,097 specimens have been examined. Of these 31.7 per cent of the gastric aspirations and 30.6 per cent of the sputa have been positive by the concentration method; 2.8 per cent of the gastric specimens and 1.3 per cent of the sputa were reported as having atypical acid-fast bacilli present.

One hundred and fifty-four specimens from patients who had received negative reports by concentration on previous specimens were injected into guinea pigs. More than half of these were pooled specimens. Two guinea pigs were injected in such cases. Of the 154 specimens, 89 per cent were negative by guinea pig inoculation and 11 per cent were positive. Of this 11 per cent (17 specimens), 4.5 per cent (7 specimens) were positive in one guinea pig and negative in the other, indicating that the organisms were very few in number. We believe that the positive results gained by careful examination of the concentrated specimens more than compensates for the time required for preparing the specimens and examining the slides, since tubercle bacilli can be demonstrated immediately in many specimens which would otherwise require guinea pig inoculation and a delay of six weeks before the bacilli could be demonstrated.

CONCLUSIONS

1. The wide variation in results obtained through the use of various methods of digesting sputa and gastric specimens and precipitating the tubercle bacilli from the digests indicates that the newer methods of handling have lit-

tle, if any, advantage over digestion with normal sodium hydroxide (2 per cent sodium hydroxide with gastric specimens or less mucoid sputa) and long centrifugation.

2. Comparable results in precipitating the organisms can be obtained through a fairly wide range of pH values (9 to 11) and surface tension readings (63 to 73).

3. Dilution with distilled water or alcohol to lower specific gravity was of no value except in the case of very viscous specimens. In such cases dilution with distilled water before digestion aids in liquefaction, and it is not necessary to increase the concentration of the digester.

4. The use of a large amount of specimen, thorough liquefaction and long centrifugation, thus securing a great concentration of the solids, are the essentials of a good concentration method.

We would like to express our appreciation to Dr. W. H. Oatway, Jr., of the Wisconsin General Hospital and to the physicians of various sanatoriums in the state for furnishing us with specimens.

A BLOOD LANCET ASSEMBLED FROM COMMON LABORATORY ACCESSORIES*

G. O. FAVORITE, M.D., AND R. D. J. CAVALLI, M.D.
PHILADELPHIA, PA.

BLOOD lancets, because of their size and constant use, are easily lost or misplaced. Internes on laboratory service are notorious for losing them. Consequently, the usual substitute for a lancet is an ordinary needle stuck through a cork. Even though such instruments are effective, it must be granted that the depth to which the needle will penetrate is not readily controllable. In addition, such an instrument often shocks the finer sensibilities of many patients. Certainly, it does not look like an instrument of precision which is expected of the medical profession.

Figs. 1-7.—1, New York Board of Health bleeding needle, gauge No. 19. 2, Needle adapter for ends of rubber tubing. 3, A second adapter to be cut at the dotted line. 4, Rubber tubing as employed for blood counting pipettes. 5, Cross section of the assembled parts. 6, Normal appearance of the instrument. 7, Shows the needle point protruded beyond the shield during action.

A practical lancet can be easily assembled from the following parts: An ordinary blood-letting needle of the New York Board of Health Type, No. 19 gauge, and $1\frac{1}{4}$ inches long (Fig. 1); two needle adapters for ends of rubber tubing (Fig. 2 and Fig. 3); and a short piece of rubber tubing of the size used

*From the Clinical Laboratories of the Hahnemann Hospital, Philadelphia, Pa., and West Jersey Hospital, Camden, N. J.

Received for publication, January 23, 1941.

on blood counting pipettes (Fig. 4). The blunt end of the needle (Fig. 1) and one of the adapters (Fig. 3) are cut off at the dotted lines. All parts are assembled and held together by the rubber tubing, as shown in Fig. 5. This figure shows the lancet in cross section with the needle in its normally retracted position. Fig. 6 shows the completed instrument, while Fig. 7 demonstrates the projection of the needle point. The rubber tubing serves a double purpose of holding the parts together and of acting as a spring for the retraction of the needle point.

Fig. 8.—The comparative size and position of the instrument.

No dimensions are given, since all parts are of standard size. The only variable is the small section of the adapter in Fig. 3. The length of this section depends on the length of the needle available, so that the latter may extend beyond its normal position to the desired distance when it is penetrating the patient's skin. Fig. 8 shows the relative size of the finished instrument.

The lancet is used by holding it between the thumb and middle finger, as shown in Fig. 8. While one end is resting on the patient's skin, the other is given a quick tap with the index finger. This maneuver will propel the needle beyond its shield to the predetermined depth. The resiliency of the rubber tubing will return the needle to its former protected position.

The lancet has been used for some time and has proved entirely satisfactory.

A MICROMETHOD OF THE WELTMANN REACTION*

PAUL B. SZANTO, M.D., AND EMANUEL OXMAN, M.D., KANKAKEE, ILL.

THE serum coagulation test, as introduced by Weltmann¹⁻³ in 1930, is a valuable aid for the differentiation between exudative, inflammatory, or necrotic processes, and fibrotic, proliferative conditions. The value of this reaction was confirmed by many German investigators.⁴⁻⁸

Recently, in this country, Levinson and associates⁹ carried out a study of the Weltmann reaction on a large series of various diseases as pneumonia, pleuritis, cirrhosis of the liver, sepsis, and especially endocarditis. Their findings confirmed the earlier reports of the worth of this test.

In a second paper Levinson and Klein¹⁰ demonstrated the importance of this test in distinguishing between exudative and proliferative types of lung tuberculosis. They say: "in tuberculosis the Weltmann coagulation test is of importance, because it can be used as a guide in the course of, and the prognosis of the disease. It reflects the tissue changes in the body." However, they write: "When exudative and proliferative changes occur in the lungs at the same time, as happens frequently in tuberculosis, the Weltmann reaction may not be of great assistance. The two divergent activities occurring at the same time result in the coagulation band, striking the normal zone." Although, the standard technique is described in the above-mentioned articles,^{9, 10} we shall repeat the description of the original method.

A 10 per cent stock solution of calcium chloride ($\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$) is prepared. From this solution various dilutions are made, ranging from 0.1 per cent to 0.01 per cent. These solutions are numbered from 1 to 10, beginning with the strongest concentration. Small test tubes, similar to those used for the Wassermann reaction, are placed in a metal rack. These tubes are also numbered from 1 to 10. Five cubic centimeters of the similarly numbered calcium chloride solution are placed in each test tube. To each tube is added 0.1 c.c. of unhemolyzed serum. The solutions are thoroughly mixed, and the tubes are placed in a hot water bath and boiled for fifteen minutes, after which time the tubes are examined. The tube with the solution of highest dilution, at which flocculation is present, is noted. Weltmann called the concentrations at which flocculation occurs as the coagulation band, and designated it as K.B. Normal K.B. is given to the reaction if there is flocculation up to and including the sixth tube. Other workers included the seventh tube as normal.

The findings of various investigators reveal that exudative and necrotic processes as pneumonia, pleuritis, caseous type of lung tuberculosis, recent coro-

Received for publication, January 22, 1941.

nary thrombosis, lung abscess, and other such conditions cause a narrowing of the K.B. (a shift to the left), or in very severe cases, an absence of any coagulation.

TABLE I

COMPARISON OF THE CONCENTRATIONS BETWEEN THE ORIGINAL METHOD AND THE MICROMETHOD

<div style="display: inline-block; vertical-align: middle; text-align: center;"> <div style="writing-mode: vertical-rl; transform: rotate(180deg);">Widening of K.B. Proliferative (Fibrous) Processes</div> <div style="writing-mode: vertical-rl; transform: rotate(180deg);">Normal K.B.</div> <div style="writing-mode: vertical-rl; transform: rotate(180deg);">Narrowing of K.B. Exudative Processes</div> </div>	NO.	ORIGINAL METHOD % DILUTION OF CaCl_2	MICROMETHOD 0.5% CaCl_2	<div style="display: inline-block; vertical-align: middle; text-align: center;"> <div style="writing-mode: vertical-rl; transform: rotate(180deg);">Shift to right</div> <div style="writing-mode: vertical-rl; transform: rotate(180deg);">Normal Zone</div> <div style="writing-mode: vertical-rl; transform: rotate(180deg);">Shift to left</div> </div>
	10	0.01	2 drops	
	9	0.02	4 drops	
	8	0.03	6 drops	
	7	0.04	8 drops	
	6	0.05	10 drops	
	5	0.06	12 drops	
	4	0.07	14 drops	
	3	0.08	16 drops	
	2	0.08	18 drops	
	1	0.1	20 drops	

In cases of fibrous or proliferative processes, as cirrhosis of the liver, fibrous type of lung tuberculosis, and chronic pneumonia, there is a widening of the K.B. (shift to the right) i.e., flocculation may be present at the eighth tube or higher.

Dees¹¹ found that this reaction is of assistance in the differential diagnosis between uncomplicated and gangrenous appendicitis. In the uncomplicated case, the K.B. is slightly less than normal, but in the gangrenous condition, the narrowing is marked.

From our experience it is our opinion that the importance of the Weltmann reaction is in the tracing of the course and complications of the disease. For this purpose frequent repetitions of this test during the course of the disease must be carried out, and these require frequent venipunctures.

Havas¹² tried to introduce a micromethod, but his technique was too complicated.

This publication presents a micromethod for the simplification of the Weltmann reaction.

TECHNIQUE

The necessary equipment consists of:

- (1) Microcentrifuge tubes of 1 c.c. capacity.
- (2) Special micropipettes, i.e., a blood collecting pipette as used for the micromethod.

- (3) A 0.1 c.c. graduated pipette. The necessary reagent is a 0.5 per cent calcium chloride solution.

Five-tenths cubic centimeter of blood, i.e., 10 drops, is drawn with the blood pipette, placed in the microcentrifuge tube, and centrifuged for fifteen minutes. One-tenth cubic centimeter of the nonhemolyzed serum is pipetted from this tube into a clean Wassermann tube. To it are added 4.9 c.c. of distilled water and 2 drops of the 0.5 per cent calcium chloride solution.

There is now the same concentration as will be found in the tenth tube in the original method. (See table for comparison of the concentrations of the original method and the micromethod.) The contents of the tube are well mixed and boiled over an open flame for one to one and one-half minutes. During this time the tube is continually shaken and observed for flocculation.

If several sera are to be examined, several tubes with the various sera and the necessary solution can be prepared. These tubes are then placed in a boiling water bath for five minutes and observed for flocculation, using either method. If no coagulation is present, 2 more drops of 0.5 per cent calcium chloride are added and the contents are boiled.

In a normal case flocculation occurs after the addition of 8 to 10 drops of the 0.5 per cent solution of calcium chloride, which compares to the sixth or seventh tube in the original method, that is, a concentration of 0.04 to 0.05 per cent.

In comparing the results of the two methods, we found that they check throughout.

The advantages of the micromethod are: (1) less blood is needed, and thus the necessary amount of serum can be obtained by just a puncture of the finger or ear; (2) venipuncture is not necessary, and for this reason daily repetition of the test is possible without much discomfort to the patient; (3) less time is expended in carrying out this method.

SUMMARY

A micromethod for the Weltmann reaction is reported. The importance of the test for the diagnosis, course, and prognosis of the different diseases are here stressed. The advantages of this micromethod are mentioned.

CONCERNING THE CHOICE OF COMPLEMENT-ANTIGEN COMBINATION FOR USE IN THE KOLMER COMPLEMENT FIXATION TEST*

I. A PRETESTING METHOD FOR COMPLEMENT SELECTION

AD HARRIS, STATEN ISLAND, N. Y.

ALMOST as important as the method of preparing antigen is the selection of satisfactory guinea pig serum to be used as complement in the Kolmer complement fixation test for syphilis. Apparently the optimal quality of complement may vary with each individual guinea pig and also may vary from time to time. A complement that is satisfactory with one lot of Kolmer antigen may give unsatisfactory results when used with another Kolmer antigen. Certain complement-antigen combinations which are unsatisfactory may be detected and eliminated by a preliminary control method for testing the combination of reagents.

As reported by Giordano and Carlson,¹ and Kolmer,² some guinea pig sera possess a component that is capable of fixing complement in the presence of Kolmer antigen at 6° to 10° C. That some complement sera may also give atypical, zonal false positive reactions with negative human serum has also been reported.²

Since this nonspecific reaction of antigen and complement may not occur at 37° C. (during the complement titration), a clue to the presence of this undesirable characteristic of some guinea pig sera is not always available until after the overnight incubation period of the test. The antigen control tube can be expected to show partial or complete inhibition of hemolysis after one hour of secondary incubation at 37° C., when complement that is readily deviated by antigen alone is employed. Under such test conditions the spinal fluid tests may be falsely positive, and some quantitative serum tests may be negative in 0.2 c.c. amounts with positive reactions in the tubes containing smaller amounts of serum. The elimination, from a herd, of guinea pigs whose sera give this type of reaction has not always solved this problem, since previously satisfactory guinea pigs have been found to yield serum having this undesirable property

*From the Venereal Disease Research Laboratory, United States Marine Hospital, Staten Island.

at a later date. Nor does the pooling of sera from many guinea pigs yield a complement of usable reactivity in all instances.

The results of the following studies have guided the formulation of a pre-testing procedure which will enable a laboratory, using either lyophilized or fresh complement, to select a satisfactory complement for use with the antigen employed in its Kolmer test.

TECHNIQUE

The Kolmer complement fixation test procedure and the test reagents used are those described in Venereal Disease Information Supplement No. 11, 1940. The guinea pigs used were healthy, male animals on a mixed diet of oats, hay, cabbage, and carrots.

PROCEDURE

The blood samples were obtained by cardiac puncture from each of 20 guinea pigs, the second and third blood samples were obtained fourteen and twenty-nine days after the initial bleeding. Sera from these bloods were tested with and without antigen to determine the degree of variability in nonspecific complement destruction that might be encountered. Two four-tube sets, containing 1.0 c.c. dilutions of guinea pig serum at 1:30, 1:33, 1:37, and 1:43, were used for each animal tested. To one of these sets of tubes was added a test dose of Kolmer antigen dilution (0.5 c.c.) plus 0.5 c.c. of saline, and to the other set, 1.0 c.c. of saline containing no antigen. All tubes were then placed in the refrigerator at 6° C. for sixteen hours. After a further incubation of ten minutes at 37° C., two units of hemolysin and 0.5 c.c. of cell suspension were added to each tube, and readings were made after a secondary incubation of one hour at 37° C. The results of these testings are listed in Table I.

In Table I the tubes containing antigen are equivalent to the antigen control tubes that would accompany a test at that complement titer, and it is noted that the destruction of complement occurring in these tubes varied within broad limits. Samples of serum, obtained from some guinea pigs on different dates, showed varying degrees of susceptibility to nonspecific destruction of complement. These results point to the fact that some guinea pigs may yield a satisfactory complement at one time and not at another. However, when the three test results are observed, it is evident that all the animals in this group did not show the same degree of serum change nor were all the changes in the same time direction. For this reason, it has been found necessary to test each complement serum at the time of bleeding rather than to rely on any previous test finding.

In order to ascertain the role of antigen in this nonspecific destruction of complement at 6° C., serial dilutions of complement were tested for hemolytic activity after having been in contact with test doses of each of two lots of Kolmer antigen (X and Y) at this temperature for sixteen hours. Control tubes, containing no antigen, were included in this test, as presented in Table II.

The dilutions of complement (1:37, 1:50, and 1:75) used in testing the anti-complementary activities of these two antigens allowed a marked differentiation to be evidenced between them. Since each of these antigens was made under similar conditions, but from different lots of beef heart powder, and since both

TABLE I

RESULTS OF ANTICOMPLEMENTARY EFFECT OF KOLMER ANTIGEN ON THE COMPLEMENT SERA OF 20 GUINEA PIGS BLED AT THREE INTERVALS

19	-	-	-	-	-	-	-	-	-	-	-	-
20	-	-	-	-	-	-	-	-	-	-	-	-

Each of the above readings was made on the tubes containing a test dose of Kolmer antigen (0.5 c.c. of 1:640 dilution). Duplicate control tubes of each of the complement dilutions, containing no antigen, gave complete hemolysis in every instance.

These tests were performed with a primary incubation period of sixteen hours at 8° C., plus 10 minutes at 37° C., and readings were made after a secondary incubation period of one hour at 37° C.

The same lot of Kolmer antigen was used throughout these three testings.

Mix 0.15 c.c. of guinea pig serum with 4.35 c.c. of Kolmer saline for 1:30 complement dilution.

antigens met with the other test demands and gave maximum fixability at the same dilution (1:640), a comparative evaluation under actual test conditions was arranged. For this purpose, serum from guinea pigs No. 1 to 13 (Table II), inclusive, was pooled and lyophilized, and will be referred to as complement A, and serum from guinea pigs No. 14 to 30 (Table II), inclusive, was pooled and lyophilized, and will be designated as complement B.

A series of 20 blood samples (7 positive and 13 negative) and 10 spinal fluids (5 positive and 5 negative) were tested simultaneously in four separate groups. Each of the antigens (X and Y) was used with each of the complements (A and B), giving the results recorded in Table III.

The tests in which antigen X and complement B were used, as well as those containing antigen Y plus complement B, and antigen X plus complement A, reacted in an orderly manner, i.e., the controls (hemolytic system and antigen) cleared in less than thirty minutes, and the tests were readable in less than one hour of secondary incubation. Antigen Y and complement A proved to be an unsatisfactory combination, since the antigen control tube did not clear, the spinal fluids gave false positive reactions, and many of the serum specimens gave atypical, zonal reactions.

These observations have aided in the formulation of the following preliminary pretest control method for observing the behavior of the complement-antigen combinations. Each guinea pig serum used, whether as fresh complement or as part of a lyophilized lot, is pretested with the antigen with which it will later be used in the Kolmer test. This may be accomplished by bleeding guinea pigs into individual test tubes, allowing these tubes to remain at room temperature until a firm clot is formed, and then placing them in the refrigerator for a few hours. After this period the clots are loosened with a wooden applicator, centrifuged at high speed for a few minutes, and the 0.15 c.c. serum needed for pretesting is removed from each tube. The tubes containing clot and serum are then placed in the refrigerator until the following morning. This testing method is outlined in Table IV.

Guinea pig sera that gave complete hemolysis in all six tubes of this test have been found to be of good quality and to have the degree of hemolytic activity required by the test author (1:30 to 1:43 for two full units). A guinea pig serum showing an equal inhibition of hemolysis in both the antigen tubes, and those containing no antigen, may be considered usable but will usually be found to have a lower hemolytic activity, as determined by the complement titration on the following day. Any sera causing a greater inhibition of hemolysis in the presence of antigen than is found in the tubes containing no antigen, may be considered as unsatisfactory when used with the testing antigen.

Using this pretesting method, more than twenty lots of lyophilized complement, satisfactory for use in the Kolmer complement fixation test, have been prepared. Each of these lots of complement was pooled from 25 to 31 guinea pigs, obtained from random herds from several breeding sources. Fifty lots of fresh complement (5 guinea pigs each), chosen in the same manner, have all been found to be of satisfactory reactivity.

DISCUSSION

Kolmer has stated that “. . . prezone and nonspecific complement-fixation tests are due to factors involving the complement employed . . .,” and it appears that the degree of this reactivity may also be influenced by some antigen component. Whereas antigen Y with complement A proved to be an unsatisfactory combination, antigen Y with complement B, and complement A with antigen X, gave satisfactory test results. Therefore, antigen Y or complement A can be considered usable if combined with a suitable complement or antigen, respectively, but are entirely unsatisfactory when used together.

When fresh complement is employed, the preliminary antigen-complement combinations of the pretest procedure can be placed in the refrigerator the afternoon the blood is drawn. This can be arranged by removing the small amount of serum needed for testing from each tube and allowing the remainder to stay on the clot until the following morning. After a reading has been made on each serum, sera found to have satisfactory reactivity can be pooled, titrated, and used without further delay. When large quantities of serum are to be lyophilized, a small amount of blood (0.5 c.c. is adequate) may be obtained from each guinea pig and tested the day before exsanguination. However, the routine used for fresh complement can be applied to complement for lyophilization if the whole blood is kept at a low temperature, during the overnight storage period, and the dehydration process is started as soon as possible after the pooling of the satisfactory sera. This pretesting procedure for complement selection is not offered as a substitute for any part of the Kolmer titrations, but rather as an adjunct to the complement titration.

SUMMARY

1. The suitability of a guinea pig complement for use with a specific Kolmer antigen may vary, within broad limits, in some guinea pigs during fourteen- to twenty-three-day intervals.
2. As demonstrated by a sixteen-hour incubation period at 6° C., the anti-complementary action of two lots of Kolmer antigen, having identical test dose titers, was not similar on all complements tested.
3. A pretest method for complement selection is described.

CHEMICAL

THE CHOLINE CONTENT OF BIOLOGICAL FLUIDS*

EDWARD EAGLE, PH.D., CHICAGO, ILL.

IN THE course of some studies on the presence and significance of choline in cortico-adrenal extracts¹ a survey was made of the available methods for the quantitative determination of choline in relatively small amounts of fluid. Although the widespread occurrence of choline and its compounds in the normal organism had been regarded as some indication of functional significance,¹ and although choline and its compounds have become increasingly important in recent years because of the unique role of an essential dietary factor as well as a hormone, little or no quantitative data can be found on the choline content of the various biological fluids.

The biological methods for choline determination depend on the conversion of the choline to its much more powerful acetic ester, and the subsequent assay of the latter on some test object by comparison with standard acetylcholine solutions. Chemically, choline forms precipitates with many reagents, but of these only three (the double salts with iodine, platinic chloride, and mercuric chloride) can be formed when the choline is in dilution of 1:2,000,000.

The original method of Sharpe² was based on the work of Stanek,³ who precipitated choline as the unstable periodide and estimated the iodine by titration with sodium thiosulfate. Roman,⁴ however, suggested the use of a stronger solution of iodine, precipitating the choline as the enneaiodide ($C_5H_{14}NOI_9$). Many investigators have used some modification of the latter procedure. The objections of this procedure are: (a) It requires at least 10 to 20 c.c. of blood. (b) Extraction by heating on a boiling water bath (presumably to split choline esters) involves the loss of free choline by decomposition, and increases the possibility of lecithin hydrolysis, resulting in newly liberated choline. (c) Dialysis for twenty-four hours against distilled water and reduction in volume of the dialysate offer excellent possibilities for the loss of choline, even up to 100 per cent. (d) Choline periodide and enneaiodide are unstable products and losses occur during evaporation to small volume. (e) The ice-cold water (0 to 1° C.) used to wash away the excess iodine dissolves some of the soluble precipitate. (f) The reagent likewise precipitates ammonium salts, stachydrine, and other extractives which cannot be removed completely without likewise affecting the precipitate.

Precipitation of the choline as the double salt with platinic chloride or Reinecke's acid may be used, and the resulting precipitates may be purified and weighed as such, checked by melting point determinations, analyzed for nitrogen, or converted to some other salt (e.g., gold salt) which can be assayed

*From the Department of Physiology, The University of Chicago, Chicago.
Received for publication, April 30, 1941.

biologically. In any case, large amounts of the original choline-containing fluid would be required for such procedure.

Addition of a saturated solution of mercuric chloride in absolute alcohol to an alcoholic solution of choline results in the formation of a stable precipitate of choline mercury chloride ($C_5H_{11}ONCl \cdot 6HgCl_2$), melting point 242° - 243° . The double salt separates out as extremely insoluble needles which can be centrifuged and thoroughly washed without loss. The mercury content can then be determined by volumetric analysis.

METHOD

The method used in the present study is essentially that of Ambo and Aoki³ and, with modifications, is given in detail as follows: Two to 5 c.c. of blood are measured into 10 to 25 c.c. of 95 per cent alcohol containing 2 to 3 drops of acid alcohol, shaken, and allowed to stand for twenty-four hours for precipitation and extraction. The mixture is then filtered, the residue is washed well with a fine stream of 95 per cent alcohol, and the total filtrate is carefully evaporated under reduced pressure to almost dryness. It is important to avoid splashing and to keep the temperature of the bath below 40° C. at all times. The residue (a few drops) is extracted three times with petroleum ether to remove fat and phosphatides, the petroleum ether being removed in each case by centrifuging and drawing off the supernatant fluid with a medicine dropper drawn out to a fine capillary. The remaining small amount of liquid is then evaporated to dryness under reduced pressure, the residue is extracted three times with small amounts of cold absolute alcohol and filtered through a very small funnel into a 50 c.c. flask (thus removing the material insoluble in cold alcohol). The filtrate is then brought to a very small volume (0.1 to 0.2 c.c.) under reduced pressure, and 1 to 2 c.c. of a saturated solution of mercuric chloride in absolute alcohol is then added. The flask is shaken well and placed in the refrigerator for twenty-four hours for complete precipitation of the choline mercury chloride.

The contents of the flasks (the precipitate and the excess mercuric chloride in absolute alcohol) are then transferred to centrifuge tubes and centrifuged rapidly at 2,800 r.p.m., and the clear, supernatant fluid is removed with a capillary medicine dropper and discarded. Absolute ether is used to wash and transfer the contents of the flask to the centrifuge tube. The precipitate is then washed six times with absolute ether, with centrifuging and removal of the supernatant fluid after each washing. It is essential that the precipitate and its container be washed completely free from excess mercuric chloride. The precipitate is then dissolved in 1 c.c. of 10 per cent potassium iodide and transferred to a flask, to which are then added 1 c.c. of 15 per cent potassium hydroxide, 3 drops of mucilage of acacia (U.S.P.) and, while shaking, 1 c.c. of 11.5 per cent formaldehyde. The free mercury separates out in fine suspension, which is first shaken well and then allowed to stand for five minutes. The mixture is then acidified with 6 c.c. of 20 per cent glacial acetic acid and 2 c.c. of 0.005 N potassium iodate solution are added from a microburette. After shaking gently to enable solution of mercury (the freed iodine combined with mercury), the excess potassium iodate is titrated with 0.005 N sodium thiosulfate, with

starch as an indicator. The 0.005 normal solutions of potassium iodate and sodium thiosulfate are freshly prepared from standardized 0.1 N stock solutions; the former are standardized at the time of titration of the regularly prepared samples.

Calculation: Each 0.1 c.c. of 0.005 N potassium iodate used combines with 0.067 mg. mercuric chloride, which is equivalent to 0.0058 mg. choline chloride containing 0.005 mg. choline.

There are several advantages of this method: (1) A small amount of the original fluid is used, so that two or more analyses may be performed on the same sample. (2) The disadvantages of choline instability in aqueous solution, and its volatility on reduction to small volume on a water bath, are avoided by the use of absolute alcohol as a solvent and distillation under reduced pressure for concentration to small volume. (3) The free choline is separated from interfering material without loss and without the possibility of liberation of bound choline from lecithin, sphingomyelin, etc. (4) The precipitant is effective even in a 1:2,000,000 dilution of choline and forms a stable, insoluble precipitate. (5) The mercury content of the precipitate may be accurately determined by standard quantitative inorganic procedure, from which the choline content is readily calculated.

RESULTS

The recovery of choline from standard solutions of choline chloride in 95 per cent alcohol is shown in Table I. The range of recovery is from 87.6 to 118.6 per cent; the average recovery for the series is 99.5 per cent.

Two standard choline chloride solutions (containing 6.66 and 19.83 mg. of choline per cubic centimeter) were submitted for nitrogen analysis in the chemistry laboratory of Billings Hospital. On the basis of the reported nitrogen content, these solutions had choline equivalents of 6.52 and 19.45 mg. per cubic

centimeter, 97.9 and 98.1 per cent, respectively, of the calculated choline content. These solutions were subsequently used to determine the yield of choline mercury chloride from solutions of known choline content (average yield 98.4 per cent), and the per cent of choline recovery from known amounts of choline mercury chloride dissolved in 10 per cent potassium iodide solution. In a series of 11 control experiments made on four such potassium iodide solutions (whose choline equivalents were 1.208, 0.683, 0.418, and 0.280 mg. per cubic centimeter) the range of choline recovery was from 88.3 to 102.3 per cent; the average recovery for the series was 93.4 per cent.

(a) Patients chewed paraffin and collected samples in bottles.

(b) Dilute saliva collected by continuous use of dental siphon.

(c) Normal persons.

(d) Patients from Out-Patient Department of Billings Hospital.

The results of choline analyses on most of the biological fluids studied are summarized in Table III. All analyses were done in duplicate; in many cases they were repeatedly performed on the same sample to determine the degree of

accuracy of triplicate and quadruplicate analyses on the same sample through a wide range of choline concentrations. The total number of analyses, including those on standard solutions and miscellaneous samples, exceeded 650. Detailed studies on blood choline variations in pregnancy and salivary choline variations during the menstrual cycle will be presented in subsequent papers.

SUMMARY

1. A modified chemical method for the quantitative determination of choline in small amounts of biological fluids has been described in detail.
2. Control studies have been made to show choline recovery from standard alcoholic choline chloride solutions, from solutions of known choline mercury chloride content, and from biological fluids to which known amounts of choline were added.
3. The choline content of 220 samples of various biological fluids is reported.

Grateful acknowledgment is made to Dr. A. J. Carlson for his cooperation throughout the course of this work.

EFFECT OF ADDED SALTS ON RECOVERY OF HIPPURIC ACID FROM URINE*

T. U. MARRON, M.S., DES MOINES, IOWA

IT HAS generally been found that hippuric acid varies in solubility in different urines, the loss on recovery being too variable for reasonably accurate clinical results of the Quick liver function test as originally outlined.^{1, 2} Efforts have been made to reduce this loss, at least to a constant value. Several years ago Berg and Mattill³ recommended the use of ammonium sulfate in student laboratory procedure for the isolation of hippuric acid from urine. A modification of their procedure has been used in this laboratory in liver function tests for three years with excellent results. Quick revised his analytical method to include the use of ammonium sulfate,⁴ but has not published the experimental work.⁵ Sodium chloride⁶ has also been employed to reduce the hippuric acid solubility in urine, but the results are not directly applicable to the conditions of the liver function test where recovery losses need to be known for a urine solution of a salt of the hippuric acid.

This paper presents a study of the effect of the addition of ammonium sulfate and some other salts on the loss in recovery of hippuric acid from urine in gravimetric procedure. Volumetric analysis is less desirable, since added salts affect the titration values, and it has been found far less precise in the hands of a number of technicians.

EXPERIMENTAL

Fresh, clear urine specimens were picked at random from routine hospital specimens in order to have representative results. Those containing more than a trace of albumin, or having unusual color, were rejected. To simulate the chemical composition of urine as it is passed in Quick liver function tests, hippuric acid (0.80 Gm.) was added as a solution of the sodium salt, prepared by neutralizing the acid with dilute sodium hydroxide. The desired amount of a salt to be tested for its effect in reducing the solubility of hippuric acid was then dissolved in the urine, and the mixture was run through a paper of rapid filtering quality, or centrifuged to remove the solids which separated. A solid phase which contained no hippurate separated from all urines when sufficient amounts of a salt were added. Therefore, the minimum quantity of a salt to be used was the amount necessary to condition hippurate-free urine to the point where no further separation of solids occurred upon acidification.

After filtration 1 c.c. of concentrated sulfuric acid was added for each 100 c.c. of urine used. Added sodium hippurate solution was considered part of the urine volume. The solution was stirred until several minutes after hippuric acid precipitated. In order to achieve constant results it was necessary to start

*From the Department of Pathology, Iowa Lutheran Hospital, Des Moines.
Received for publication, May 12, 1941.

crystallization by friction between the beaker and stirring rod. One to four hours later the precipitate was collected quantitatively on a weighed filter paper over suction. The filtrate was used to wash the beaker. The precipitate and the inside of the funnel were washed with 15 c.c. of distilled water (25° C.) from a medicine dropper. This left less than 0.01 Gm. of the precipitating agent on the filter and had a negligible effect on the quantity of hippuric acid. Weight of the precipitate was taken after it had dried twelve hours at 37° C. A 5.5 cm. No. 4 Whatman filter on a 67 mm. Buchner porcelain funnel fitted into a side-neck test tube was found convenient, because all the solid settled on the paper, and any loss could be seen in the tube and recovered.

DISCUSSION AND RESULTS

By this method the true solubility of hippuric acid in treated urine was not determined, but the loss incurred in actual procedure was ascertained. The variations in recovery from different specimens is probably largely due to the inability of added salts to abate entirely the effects of urinary colloids on crystallization.

TABLE I

LOSS OF HIPPURIC ACID IN URINES TO WHICH SALTS HAVE BEEN ADDED TO FACILITATE PRECIPITATION

SPECIMEN	URINE VOLUME (C.C.)	HIPPURIC ACID LOSS (GM./100 C.C.)	SPECIMEN	URINE VOLUME (C.C.)	HIPPURIC ACID LOSS (GM./100 C.C.)

Average		0.100			

Table I gives the hippuric acid loss for 21 different urine specimens to which 35 Gm. of ammonium sulfate were added for each 100 c.c. volume. This is the minimum quantity of that salt practical for use; more of it has no advantage. For clinical accuracy 0.1 Gm. can be added to the amount of hippuric acid recovered from each 100 c.c. of urine by the method outlined here. This holds true for urine volumes to 200 c.c. without concentration. However, the necessity of concentrating urine from patients with copious output is not obviated.

Magnesium sulfate is a more economical salt to add to urine. Experimental results with the use of this salt show slightly greater average loss per 100 c.c.; nevertheless, the data in Table I indicate it is a good agent to use. Fifty grams per 100 c.c. of urine are necessary. Magnesium sulfate in this concentration is still far enough from the saturation point that it does not readily crystallize out. An average loss of 0.127 Gm. per 100 c.c. of urine is to be added to the hippuric acid recovery if magnesium sulfate is employed at 50 Gm. per 100 c.c.

Four determinations with 35 Gm. of sodium sulfate per 100 c.c. of urine gave an average loss of 0.158 Gm. of hippuric acid per 100 c.c. Addition of more of this salt was found impractical.

Thirty grams of sodium chloride per 100 c.c. of urine reduced the loss to 0.1 Gm. or less. Since it is more difficult than the other salts used to wash from the hippuric acid, it probably contributed to the recovery in the trials made. Moreover, the effective concentration of salt is so close to its saturation point in urine that difficulty is experienced with its crystallizing from solution and on the filter. Its use in either volumetric or gravimetric method for hippuric acid lengthens the procedure because heat is necessary to effect solution, and this must be followed by a cooling period.

SUMMARY

Of four salts tested for reducing the solubility of hippuric acid in urine to a constant value, ammonium sulfate was found to be the best. The loss was reduced to an average of 0.1 Gm. per 100 c.c. of urine under the conditions of the Quick liver function test, using gravimetric procedure.

A NOTE ON THE USE OF TÖPFER'S REAGENT IN GASTRIC ANALYSIS AFTER TEST MEALS OF MILK, CREAM, OR SOYBEAN BISCUITS*

GEORGE B. LAWSON, M.D., ROANOKE, VA., AND
J. R. LEONARDS, M.S., AND A. D. PRATT, PH.D., BLACKSBURG, VA.

IN TESTING a patient with duodenal ulcer with various foods to see whether any of them would decrease the gastric acidity, it was found that milk would give about one-half as much free acid as the bread test meal, using Töpfer's reagent as the indicator. Soybean biscuits also decreased the acidity. Casein and whey were then used, but neither of these showed any apparent change in the total free acid. Finally, sweet cream was fed after which no free acid was indicated by Töpfer's in the fractional test meal. Likewise, Töpfer's failed to indicate change of acidity when an excess of hydrochloric acid was added to cream *in vitro*.¹ Since the salts of milk should give it more buffering action than cream, the problem was investigated further.

Preliminary experiments on the titration of milk and cream with hydrochloric acid, using Töpfer's reagent as the indicator, suggested that the indicator did not function properly in the presence of these substances. To check the action of the indicator, potentiometric titrations were carried out using a Leeds and Northrup pH meter with glass electrode. Stepwise additions of N/10 hydrochloric acid and sodium hydroxide produced the expected changes in pH. With phenolphthalein as the indicator sodium hydroxide caused the solution to turn pink at pH 8.5. However, with Töpfer's reagent as the indicator the solution remained yellow even after the acidity was lowered to pH 1.5. Further addition of 2 ml. of concentrated sulfuric acid caused the solution to turn red, which should have occurred at pH 2.9.

A sample of milk was acidified with N/10 hydrochloric acid to pH 2.5. Töpfer's reagent was added, and the indicator was still yellow. After centrifuging it was noted that the fat and protein layer had a yellow color, while the milk serum was slightly pink. On adding one more drop of Töpfer's reagent to the milk serum it turned red.

These results indicate that the fat and/or proteins of the milk interfere with the use of Töpfer's reagent as an indicator in the titration of milk with hydrochloric acid. It was now thought desirable to determine whether the fat or the protein was responsible for this interference.

(a) Fresh skim milk was obtained which contained less than 0.02 per cent fat. On titration with hydrochloric acid, Töpfer's reagent functioned normally and changed at the proper pH. Thus it appears as though the casein is not the interfering factor.

(b) A sample of 20 per cent cream was acidified in the presence of an excess of Töpfer's reagent and centrifuged. The serum was pink, but the fat-

*From the Jefferson Hospital, Roanoke, and the Nutrition Laboratory, Dairy Husbandry Department, Virginia Polytechnic Institute, Blacksburg.
Received for publication, May 17, 1941.

protein layer had a yellow color. The casein was then removed by washing three times with N/10 sodium hydroxide, once with water, twice with N/10 hydrochloric acid, and once again with water. After this treatment the fat layer still retained the yellow color.

It appears probable that in this two-phase system the ionization of the Töpfer's reagent in the fat phase is negligible.

TITRATION OF SOYBEAN MEAL

Ten grams of soybean meal were suspended in 90 ml. of distilled water and titrated with hydrochloric acid in the presence of Töpfer's reagent.

During the titration with this acid, Töpfer's reagent remained yellow even after the pH was as low as 2.1 as determined potentiometrically. Again on the addition of 1 ml. of concentrated sulfuric acid, the reagent turned red. In this case, however, it was noted that if during the titration, 1 drop of the solution was removed and tested with Töpfer's reagent on a spot plate, the indicator turned red at the proper pH. This again indicated that some constituent of the soybean meal interferes with the use of Töpfer's reagent.

The pH range over which Töpfer's reagent changes color is wide, and thus even at best the use of the reagent is inaccurate. This fact, coupled with the interfering substances in milk, cream, soybean flour, and possibly other common foodstuffs, makes the use of Töpfer's reagent inadvisable in gastric analyses involving these foods. However, in routine gastric analysis, where the meal of bread and water is fed, it was found that Töpfer's reagent was satisfactory and agreed with potentiometric titration.

A NOTE ON THE DECOMPOSITION OF NESSLER'S SOLUTION*

W. E. JAMES, M.D., F. A. SLESINSKI, M.S., AND H. B. PIERCE, PH.D.
BURLINGTON, VT.

RECENTLY we noticed that freshly prepared Nessler's solution on standing a short time in rubber-stoppered bottles formed a yellow precipitate. New solutions of Nessler's stock reagent and 10 per cent sodium hydroxide were prepared and mixed, and again cloudiness and precipitation occurred.

Another set of reagent bottles was obtained, and cork stoppers were used in place of rubber. No precipitation was observed with either the old or the new solutions. When rubber stoppers were substituted for cork, precipitation was noted. While trying to locate the cause of our trouble, we remembered that we had removed the bloom from rubber stoppers with acetone according to the method of Matviak.¹ The stoppers were not immersed in acetone but were wiped with a cloth moistened with acetone. They were washed thoroughly in water, dried and exposed to room air for a day or two prior to their use. No odor of acetone was detected from these stoppers.

The addition of a drop of acetone to Nessler's reagent caused immediate precipitation, and a like result was obtained when acetone vapor was blown over the mouth of a test tube containing Nessler's solution. Fumes arising from the use of acetone in the laboratory produced cloudiness, showing the extreme sensitivity of Nessler's reagent to acetone.

DETERMINATION OF CALCIUM IN BILE*

CECILIA RIEGEL, PH.D., AND WILLIAM KASINSKAS, B.S., PHILADELPHIA, PA.

THE wet ashing method with nitric acid and perchloric acid, as described for grains by Giesiking, Snider, and Getz,¹ and for tissues by Buell,² may be applied to bile. It gives a water-soluble ash which is very satisfactory for the determination of calcium.

The procedure is as follows: Add to from 1.0 to 3.0 c.c. of hepatic bile in a 50 c.c. beaker twice the quantity of nitric acid and an equal amount of perchloric acid. For gall bladder bile use 0.5 to 1.0 c.c. samples and add four times the amount of nitric acid and twice the amount of perchloric acid. Heat to dryness at low heat on the electric hot plate. Take up the residue in water

Received for publication, July 15, 1941.

and transfer quantitatively to a 15 c.c. centrifuge tube, keeping the volume below 6 c.c. Add a drop of methyl red, enough ammonia to make the solution alkaline, and then 10 per cent acetic acid to approximately pH 4 to 5. Add 1 c.c. of ammonium oxalate (4 per cent) and proceed as in the Clark-Collip method for determination of calcium in blood.

Table I gives the results of some analyses.

*A solution containing 1 mg. of calcium per cubic centimeter was used in all instances where calcium was added to the bile.

Usually the residue obtained is white in color and dissolves readily in water. Occasionally a brown residue is obtained, which may be digested to whiteness by adding nitric acid and perchloric acid again. This is not necessary, however, as good results are obtainable even when the residue is slightly discolored. We have also found that if large amounts of organic material are present, as with gall bladder bile, the digestion mixture may turn dark brown or black when it reaches a small volume. If this happens, a second, or even a third, digestion with nitric acid and perchloric acid is necessary. In such instances care should be taken not to allow the dark mixture to evaporate to dryness since slight explosions may occur.

FURTHER NOTES ON THE COLORIMETRIC DETERMINATION OF INULIN IN BLOOD AND URINE*

ALF S. ALVING, M.D., JACK FLOX, B.S., ISADORE PITESKY, B.S., AND
BENJAMIN F. MILLER, CH.E., M.D.,† CHICAGO, ILL.

WITH the development of a practical clinical method for measuring the glomerular filtration rate in man, clinical laboratories have been called upon to determine the concentration of inulin in blood and urine.¹ For this purpose a simple direct colorimetric method was described by Alving, Rubin, and Miller.² Certain difficulties which have been experienced by some laboratories in the routine application of this method may be overcome by the use of the following modifications and precautions.‡

Reagents.—Diphenylamine reagent. This reagent is now prepared as follows: To 250 c.c. of absolute ethyl alcohol in an Erlenmeyer flask 100 c.c. of C. P. concentrated hydrochloric acid are added. The mixture is then quickly cooled to room temperature. The change in volume resulting from the mixture of hydrochloric acid and alcohol is disregarded. Immediately before using the reagent, 20 c.c. of diphenylamine (from Merek or G. Frederick Smith Co., melting point 52.5° to 53.3° C.) in absolute alcohol are added. The alcohol-diphenylamine solution is made by adding 20 c.c. of absolute alcohol to 3.4 Gm. of diphenylamine in an Erlenmeyer flask. The final reagent is conveniently made from this solution and the acid-alcohol mixture by pouring them back and forth a few times from one Erlenmeyer flask to the other.

When prepared as described here, the reagent gives an appreciably deeper color in the reaction with inulin than the reagent employed previously. In

*From the Department of Medicine, University of Chicago.

Received for publication, August 18, 1941.

†This work was aided by the Douglas Smith Foundation and the Kenneth Smith Fund of the University of Chicago.

‡Some precautions and modifications have already been described.^{2, 4}

order to keep the blanks as low as possible we prefer to prepare the required quantity of this reagent fresh each day.

Removal of Fermentable Carbohydrate.—Commercial inulin solutions, which are satisfactory for intravenous clinical use, contain appreciable amounts of a non-inulin fermentable material. Since this substance gives additional blue color with diphenylamine, *it is essential that it be removed from both blood and urine samples by fermentation.* This procedure should be employed even when Benedict's qualitative test for reducing substances is negative on the urine.

After fermentation of the samples of plasma or urine, and removal of yeast cells by centrifugation, only the clear supernatant fluid is used for preparing protein-free filtrates.

A special, starch-free yeast can be obtained from the Fleischmann Yeast Co. It is necessary to wash this yeast as originally described.² It is worth while to use the special, washed yeast because with it the blank values are markedly reduced. For example, we obtain blank values on plasma below 0.5 mg. per 100 c.c. inulin equivalent.

Development of Color.—Reaction tubes. Improved, pressure-resistant tubes, manufactured by Kimble Glass Co., have the following specifications: "Special, round bottom, screw cap vials, 19 to 20 mm. outside diameter and 110 mm. long; made of N-51A No. 2 weight glass; one end threaded to fit an 18 mm. G.C.A. cap, other end round bottom. Vials must have standard fire-finished flat tops. Glass must be evenly distributed; vials must be lehrred; lips must be square but not ground. Vials must have sandblasted spot as close to the shoulder as conveniently possible." New glass reaction tubes must be washed with soap and hot water before use in order to remove oily films from the glass. Then to remove traces of soap the tubes are rinsed thoroughly in hot water, filled with an acid-alcohol mixture similar to that described under "Reagents," stoppered, and heated in boiling water for at least fifteen minutes. After final rinsing with distilled water, these new tubes give satisfactory results. During subsequent use soap should not be employed; it is sufficient to clean the tubes by flushing with hot water, soaking in cleaning solution for at least one hour, and rinsing finally with distilled water.

Rubber liners. The use of replaceable, white rubber liners was recommended originally for the screw caps of the reaction tubes. The liners that we first obtained contained very little sulfur, which could easily be removed by boiling the liners in a dilute solution of sodium hydroxide. Liners must be free of sulfur which reacts with diphenylamine to produce a blue color similar to that given by inulin. When rubber liners are used, they must be cleaned in hot alcohol and rinsed in distilled water between determinations. If the glass reaction tubes or rubber liners are dirty, or are contaminated by traces of soap, the results will be less reproducible.

Plastic liners. It has become increasingly difficult to obtain durable rubber liners that are low in sulfur content. Because there is little prospect that this situation will improve, we have tried to use, with even more satisfactory results, 18-400 black phenol molded improved Lusterseal caps with glued-in Pliofilm pulp or waxed Vinylite pulp liners. The caps and liners do not have to be cleaned

before use. They must be discarded after being used once, but are cheap if purchased in quantity. Liners for this type of cap cannot yet be obtained separately. Satisfactory caps and liners are manufactured by Owens-Illinois Glass Co.*

Estimation of Color Intensity.—A No. 635 filter is somewhat more suitable for measuring light transmission than the No. 660 filter employed originally.†

Calibration.—Standard inulin solutions may be kept for months without deterioration if the inulin is dissolved in saturated benzoic acid. A standard, equivalent in color development to a 1 per cent solution of inulin, may be obtained from the United States Standard Products Co., Woodworth, Wis. This concern has also developed a satisfactory preparation of inulin for clinical use.

Determination of Blank Value of Reagents.—When several sets of analyses are performed, three blanks on water plus reagents, omitting yeast, or three tubes containing inulin of known concentration plus reagents, should be heated in each water bath with the solutions of unknown concentration in order to determine the “center-point setting” of the galvanometer.

The “center-point setting” may be determined by means of an inulin solution of known concentration as follows: With the known solution in the Evelyn colorimeter, the galvanometer is adjusted to correspond to the previously determined reading of the known solution on the calibration curve. The known solution is then taken out, and the galvanometer reading without any tube in place is taken as the “center-point setting.”

The “center-point setting” can be determined a little more accurately for unknown solutions of high inulin concentration (low galvanometer reading) by the simultaneous analysis of a known solution containing 3.5 to 4.5 micrograms of inulin per cubic centimeter; but for unknowns of low concentration the use of blank analyses on water plus reagents is preferable, and for making the original calibration curve, it is imperative.

RESULTS

In analyzing inulin solutions of concentrations greater than 0.01 mg. per cubic centimeter, a small amount of blue precipitate is occasionally formed in the colorimeter tube. Ordinarily the error introduced by this precipitate is small, but the formation of the precipitate can be prevented by the proper dilution of samples before analysis. Whenever possible the unknown solution should be diluted to give a reading between 30 and 70 on the galvanometer scale of the Evelyn photoelectric colorimeter.

It must be emphasized that for most reproducible results the time of boiling should be standardized to exactly sixty minutes. The reaction is stopped by cooling the tubes immediately to room temperature. The colorimetric determinations should be carried out approximately thirty minutes after the tubes are removed from the boiling water bath.

*Reaction tubes, caps, and liners may be obtained from regular laboratory supply houses. We obtain our supply through E. H. Sargent and Co., Chicago, Ill.

†Filter No. 635, supplied by Rubicon Co., Philadelphia, Pa., permits transmission of approximately 95 per cent of the light between 618 and 650 millimicrons, the approximate mean wave length of the transmitted band being 635 millimicrons.

In performing inulin clearances, the effect of analytical errors on the clearance values can be reduced to a minimum by heating corresponding plasma and urine samples together in the water bath, instead of analyzing plasma and urine samples at different times.

A CHEAPER NESSLER'S REAGENT BY THE USE OF MERCURIC OXIDE*

L. F. WICKS, ST. LOUIS, MO.

INTRODUCTION

WITH the general rise in the price of chemicals at the present time, any economy in preparing large batches of Nessler's reagent should be of interest to most laboratories. Formation of the desired double halide from the oxide of mercury (and twice the usual equivalent of potassium iodide) is cheaper than its preparation from the very expensive mercuric iodide, or even from elementary iodine and mercury.

Nessler's reagent, as we all know, is essentially a strongly alkaline solution of a certain double iodide of potassium and mercury. Reaction with ammonia yields a colloidal¹ compound which in dilute solutions is evident as a yellow to brown color, and in less dilute ones (where the concentration of ammonia exceeds a few milligrams per hundred cubic centimeters) as a precipitate.

There is only slight doubt as to the composition of the effective double iodide in this old² and much-modified reagent. It is generally agreed to be formed from the equivalent of two moles of potassium iodide to each one of mercuric iodide: $2KI \cdot HgI_2$ or K_2HgI_4 . Friend³ leaves the matter uncertain, but Treadwell and Hall⁴ give the above salt in an equation for nesslerization. Mellor,⁵ in his familiar *Comprehensive Treatise*, submits the usual mass of conflicting statements, but later (in his one-volume edition⁶) he also presents K_2HgI_4 in an equation and states that the effective ratio of mercury to iodine should be 1:2.54, which corresponds exactly to the above compound. Yoe⁷ likewise agrees, as do Latimer and Hildebrand.⁸

*From the Research Department of the Barnard Free Skin and Cancer Hospital, St. Louis. Received for publication, July 14, 1941.

The double iodide evidently dissociates scarcely at all to give mercuric ions, for the addition of hydroxyl ions in considerable concentration may produce no precipitate of mercuric oxide. Ionization must largely occur thus:

In the presence of ammonium ion or ammonia as well as of alkali, this complex ion reacts to yield a peculiar, highly colored compound, probably a polymer. Equations such as these are given:

The chromatic substance, "mercuric hydroxiodamide"¹⁵ or "oxydimercuric ammonium iodide,"¹⁶ is of very doubtful composition. It is said⁴ to be the iodide of "Millon's base," the white product obtained when aqua ammonia acts upon mercuric oxide. There is a host of formulas given for Millon's base and still more for Nessler's precipitate. Many texts are agreed that the latter compound has an *empirical* formula of $\text{NH}_2\text{Hg}_2\text{OI}$,⁹ which is variously written as: $\text{OH}\cdot\text{Hg}\cdot\text{NH}\cdot\text{HgI}$,³ $\text{NHg}_2\text{I}\cdot\text{H}_2\text{O}$,^{4, 8, 22} $\text{NH}_2\cdot\text{Hg}\cdot\text{OHgI}$,¹⁰ $\text{HgOH}\cdot\text{NH}\cdot\text{HgI}$,⁶ $\text{HgO}\cdot\text{Hg}(\text{NH}_2)\text{I}$,⁷ etc. Franklin¹¹ in 1907 also gave $\text{Hg}_2\text{NH}_2\text{OI}$, but later¹² changed this to either $2\text{HgO}\cdot\text{NH}_3\cdot\text{H}_2\text{O}$ or $4\text{HgO}\cdot 2\text{NH}_3\cdot\text{H}_2\text{O}$. The most recent attempts at analyzing this baffling compound were by Nichols and Willits,¹ who claim that it is $\text{NH}_2\cdot\text{Hg}_2\text{I}_3$, and give this expression for nesslerization:—

The necessity for alkali is not obvious in their equations. The colored substance, the authors further state, is highly insoluble and forms an electro-negative suspensoid. This lyophobic nature is certainly indicated by the great gain in stability when soluble gums¹³ are previously added to nesslerized solutions.

If we assume then that the effective double iodide is $2\text{KI}\cdot\text{HgI}_2$, and calculate the ratio of potassium iodide to mercuric iodide for various Nessler's reagents, we see that in the more satisfactory preparations this ratio, by design or by chance, closely approaches our theoretical ratio or slightly exceeds it for the sake of stability. $2\text{KI} : \text{HgI}_2 = (2 \times 166.0) : 455.4 = \text{approximately } 332/455$, or about 0.73.

REAGENT	REFERENCE	% KI	% HgI_2	RATIO	% NaOH
Frerichs and Mannheim	14	2.5	3.5	0.71	15 (KOH)
Folin and Denis	15	2.25	3.0	0.75	2.0
Folin-Wu	16	1.125	1.50	0.75	7.0
Bock-Benedict	17	7.0	10.0	0.70	10.0
Koch-McMeekin	18	1.02	1.38	0.74	8.3
Vanselow	19	3.49	4.55	0.77	11.2 (KOH)

In fact, if one deviates very far from this figure, the sensitivity of the reagent decreases enormously. For example, when employing equal molarities of the potassium and mercuric iodides, a color will not develop with ammonia even when the reagent is strongly alkaline. It is desirable that there be just sufficient excess of potassium iodide to keep the mercuric iodide in solu-

tion; but little more or sensitivity will suffer. Vanselow¹⁹ recommends a 5 per cent excess of potassium iodide over that required to form the hypothetical K_2HgI_4 , and thus the ratio in his reagent is 0.77. Other factors also reduce the sensitivity. With insufficient free hydroxyl ions, no color will develop at all, but great excess of alkali will produce a precipitate, probably mercuric oxide. Certain foreign salts, such as bicarbonates⁴ or chlorides,¹⁵ lower the intensity of the Nessler color. Temperature is also stated²⁰ to be rather influential.

The oldest method of preparing Nessler's reagent is the somewhat arbitrary one of adding an excess of potassium iodide to a saturated solution of mercuric chloride²¹ (and then considerable base).

This technique is still given in many texts,^{9, 22} but it is best suited for water analysis and such instances where the concentration of ammonia is quite low. Otherwise, the potassium chloride adds unwanted electrolyte which increases the tendency of the suspensoid to precipitate.

The time-honored procedure^{15, 16, 18} of reacting metallic mercury with a tri-iodide solution yields the compound desired, but it is inconvenient and it appears that it is becoming obsolete.

When mercuric iodide, free of such impurities as the sulfide and mercurous compounds, became readily available, the modification of dissolving mercuric iodide in strong, hot potassium iodide solution was adopted.^{14, 17}

Dawson,²³ in his equilibrium researches, found evidence that in solutions where the dissolved mercuric iodide is relatively low, the chief complex electrolyte is K_2HgI_4 .

The proposed method is this:

Here we have two end products, but both are needed for the reagent (the amount of alkali formed supplies only a fraction of that required). Rupp and Schirmer cited by Mellor⁵ prepared the double iodide by the last reaction and proposed it as a method for standard alkali.

Friend,³ and Latimer and Hildebrand,⁸ also give the above equation as a reaction of mercuric oxide. This reaction was once used^{24, 25} as a technique for providing standard alkali from a known weight of the pure oxide. Strangely, after a rather thorough search of the literature, I have encountered no mention of the utilization of this reaction of mercuric oxide to prepare Nessler's reagent.

PROCEDURE

Directions are given for the substitution of mercuric oxide in the preparation of the Koch-McMeekin¹⁸ solution only, as this modification of the old Folin-Wu formula is probably the best Nessler's reagent as regards sensitivity, stability, and economy of materials that is in general clinical use. I have

prepared this formula (and others) by the authors' original method, with mercuric iodide, and with the oxide, and have found the three solutions apparently identical in excellence and composition.

Dissolve 19.1 Gm. of A.R. (analytical reagent quality) red mercuric oxide powder in a solution of 60 Gm. of A.R. potassium iodide in about 100 c.c. of ammonia-free water. Heat on an electric hot plate and stir until clear. The last bit of the solid dissolves with difficulty. Cool the deep yellow solution of the double iodide, make to 200 c.c., and then stir into 975 c.c. of pure 10 per cent sodium hydroxide. This 1,175 c.c. volume of the original Koch-McMeekin reagent can be rather inconvenient. A liter could be prepared by using somewhat less of the iodide stock solution, thus: pour 160 c.c. of 50 per cent sodium hydroxide solution into about 600 c.c. of ammonia-free water. Add only 170 c.c. of the above iodide stock (with stirring) and dilute all to a liter with redistilled water. The objection may be raised that some of the iodide stock is left over. To avoid this, we can use a stock solution somewhat less concentrated than the original:

Dissolve 16.2 Gm. of A.R. red mercuric oxide in a solution of 51 Gm. of A.R. potassium iodide in 100 to 150 c.c. of ammonia-free water. Heat on an electric hot plate and add the powder in small portions, stirring until all is dissolved. Then dilute the double iodide solution thus obtained with about an equal volume of redistilled water and let cool. Dilute also 160 c.c. of clear (centrifuge if necessary) 50 per cent sodium hydroxide solution with about one-half liter of pure water. Pour in the iodide stock and make to one liter.

Red mercuric oxide is recommended since it costs somewhat less than the yellow form. The latter differs only in being of smaller particle size⁸ and should be quite as satisfactory chemically, and perhaps more readily soluble.

How familiar is the phrase, "let stand to clear," but if the Nessler's reagent is prepared of pure materials, it is almost perfectly free of turbidity at once. Much purchased distilled water, especially that from raw river water, contains a surprising amount of ammonia and organic matter. If this is so, redistil that used for the reagent from an acid-permanganate solution. (In the interest of safety, add only enough potassium permanganate to maintain a decided purple color and just a small percentage of sulfuric acid.) Carbonate-free sodium hydroxide will be assured if one uses the convenient 50 per cent solution.

MEDICAL ILLUSTRATION

THE APPLICATION AND WEARING OF FACIAL PROSTHESES*

CARL DAME CLARKE, PH.D., BALTIMORE, MD.

NUMEROUS articles have appeared in the medical and dental literature with regard to the manufacture of moulage prostheses or artificial parts to be worn on the human face and body. The most outstanding of these are by Kazanjian, Rowe, and Young,¹ Berewitsch,² Zinsser,³ Clarke,^{4, 5} and Bulbulian.^{6, 7} The majority of the prostheses considered in these articles were artificial noses, ears, cheeks, and eyes in which parts of the orbits and lids have been reconstructed rather than false teeth and gums that fit adjacent to mucous membrane. The prostheses to be discussed by me fit primarily next to skin surfaces and are held in place by mechanical devices, such as eyeglass frames, or an adhesive, such as gum mastic, dissolved in the proper solvent. The material already published did not explain in detail the actual wearing of prostheses. Instead, the manufacture of the prosthesis was considered, and methods were given for attachment by mechanical devices or by an adhesive. These articles left the prosthetist and his patient to determine by experimentation and experience the most comfortable adhesive mixture to use and the length of time required to rest the tissues. For example, some wearers of artificial parts on the face prefer to wear them continuously for a few days, others prefer to remove them every night. This depends largely on the extent of the restoration and the materials used.

I have been associated with two physicians who have had prostheses made months ago and are wearing them at the present time. Since these men themselves have facial restorations, they are exceptionally well qualified to know from firsthand experience the problems that arise during the application and wearing of prostheses. Furthermore, as physicians they understand the nature of any irritations that may begin and know how to correct them. One of these cases represents a partially restored nose that was required after the removal of an epithelioma; the other is a partially restored ear designed to correct a defect resulting from an accident. I am, therefore, indebted to these two men, who prefer to remain anonymous, for the following information and description of their actual experiences during the wearing of their respective prostheses.

PRECAUTIONS TO BE TAKEN IN MANUFACTURE OF PROSTHESES

In the manufacture of a prosthesis it is essential to use the utmost care in the preparation of both surfaces of the material, that is, the outer or visible surface and the surface that will come in contact with the skin. The exposed

*From the Department of Art, University of Maryland School of Medicine.

contours should be regular, smooth, and lifelike, with the correct proportions and color. The contact surface should be smooth, without sharp points or granular areas that do not make complete contact. It must fit snugly and completely to the skin on which it will be attached; any irregularity or depression in the skin must be filled with a corresponding negative impression on the moulage. It is for this reason that flexible materials, such as latex and gelatin-glycerin-sorbital mixtures are more practical than the hard, firm, unyielding substances. Metal, vulcanite, and the synthetic resins, such as vernonite and vinyl acetate, belong to the latter group.

Surface area should not be sacrificed for cosmetic effect in preparing the contacting surface. In other words, the surface area should be sufficiently extensive to approximate a considerable portion of the skin area when applied to it with the adhesive substance; otherwise the border of the prosthesis will not approximate closely the dermal structure. The edges will be more apparent and fixation will be unsatisfactory. This statement from the wearer of a prosthesis came as a surprise, because I labored under the assumption that the smaller the skin surface covered by an artificial part, the more realistic the effect. In his opinion sufficient skin surface must be covered to make the artificial part feel comfortable and at the same time give complete assurance that it will not fall off. Naturally, this matter should be tempered according to the size and weight of the prosthesis and the strength of the adhesive used. When making a prosthesis, the seam or junction between the natural and artificial skin surfaces should come at points, lines, or areas that will prevent detection as far as possible. Folds and character lines within the skin surface offer the best areas for forming the joining lines. When such details are considered, the moulage maker may take advantage of them in making the prosthesis to produce surfaces that will support the weight of the prosthesis and at the same time escape detection.

ADHESIVE MATERIALS

Bercowitsch² and Zinsser³ advised the use of gum mastic dissolved in alcohol as an adhesive to hold a nose or an ear prosthesis to the skin surface. In trying this mixture I found that the alcohol dried too slowly from the mastic to effect satisfactory adhesion. Furthermore, the mastic turned milky in the presence of moisture, an effect known as *bloom* in the field of art. Since gum dammar does not react in this manner, I substituted it for the mastic.

Gum dammar and gum mastic possess the following qualities: (1) They are transparent when in solution. (2) They are insoluble in water. (3) They are non-irritating. However, I have heard of one case in which the gum mastic solution was blamed for causing a skin rash at the place where the prosthesis joined the skin. I am inclined to believe that this was the result of an idiosyncrasy to the gum, or that there was a mechanical irritation created by removing the part too frequently. In numerous other instances the gum mastic was used properly over a period of years without any detrimental effect. (4) An excess of either gum dammar or gum mastic or any quantity of these which remains dried on the skin or the prosthesis may be removed with a 70 per cent solution of alcohol. (5) These ingredients are inexpensive, a year's supply costing only a few cents.

(6) Both gum mastic and gum dammar are not affected by normal temperature changes. Gum dammar is not affected by excess humidity, and gum mastic is not likely to be changed to any great extent. The wearer may notice that the gum mastic will bloom when it is applied in rainy weather. However, this is of little consequence. (7) A normal prosthesis may be attached by the use of these materials in a few minutes, fifteen minutes at the most.

To overcome the slow drying of the alcohol, as recommended by Bercowitsch and Zinsser, I used a mixture of equal parts of alcohol and ether in which the gum dammar was dissolved. The patient was advised to paint the gum dammar solution on the surface of the prosthesis that was to come into contact with the skin surface, then put the prosthesis in place and hold it for a few minutes until complete and comfortable adhesion was effected. This required only a few minutes. I instructed the patient to increase the amount of ether in the solution if he wanted quicker adhesion, and to add more alcohol if the adhesion took place too quickly or dried before the prosthesis could be put in place.

This reasoning seemed logical to me, but I found that one wearer preferred to use ether entirely as a solvent for gum mastic. The fact that this gave satisfactory results over a period of years speaks for itself. The wearer claims that the gum mastic is more effective when dissolved in ether, and if kept in solution will prove a more uniform and adequate adhesive agent than if prepared for each individual application. It is best applied to the prosthesis by means of a medicine dropper, and the density of the solution should be such that it can be drawn into the dropper with ease. The ether evaporates very readily from the solution if the container is left open for any length of time and should be replaced from time to time if the mixture becomes too thick. In the event the solution becomes too thin, additional gum should be added. I always prepare a bottle of the gum solution and give it to the patient with his prosthesis. Instead of the medicine dropper, I use a bottle with a stopper that contains a small bristle brush. This brush is used to apply the adhesive to the contacting surfaces. After the adhesive is applied, the prosthesis is put in place and held with firm, constant, and regular pressure until the solvent evaporates from the gum and complete adhesion takes place.

WEARING OF THE PROSTHESIS

The prosthesis, after its application, can usually be worn for about three days. The gum mastic then becomes only loosely adherent and removal at that stage is simple, only a small amount of traction being necessary. If the prosthesis is removed at such time there will be no skin abrasions or irritations. The prosthesis may then be cleaned with alcohol and replaced. There is no reason why a prosthesis made of latex or a gelatin-glycerin composition should not be worn at night. As a matter of fact, it is unwise to detach it too frequently, particularly when it is attached firmly to the skin. Of course, the size of the prosthesis and the material from which it is made may have some bearing on these instructions. If the prosthesis is attached to the eyeglass frame it may be possible to dispense with an adhesive altogether. This depends upon the location and extent of the lesion and the size of the prosthesis.

CARE OF THE SKIN

When the prosthesis is removed, the dried nonadhesive debris of the gum-solvent solution should be cleaned away carefully with a 70 per cent alcohol solution. Gentle massage with a soft cloth dampened with alcohol is all that is necessary. The generous application of alcohol to the surrounding skin surface with the fingers will be found comforting and helpful. It will also be found practical and wise to leave off the prosthesis occasionally for several hours, as during sleep. The application of tincture of green soap before this replacement is made may aid in protecting the surface.

In a recent communication one of these physicians supplied the following information: "I have been using the moulage prosthesis for two years and during this period have had absolutely no skin or other reaction of any sort in spite of the fact that my skin is unusually sensitive. My prosthesis is most satisfactory and is not noticed by the public; however, upon a few occasions some of my medical friends have asked me who did the plastic operation and were wondering from what area the skin was removed. It has been my choice to remove it each night, replacing it in the morning, which is done in less than a minute's time."

If the principles here outlined are followed carefully, a satisfactory wearing of the prosthesis will be experienced with the least amount of physical and mental discomfort and the maximum in cosmetic efficiency.

 Erratum

On page 1799 of the August number of the JOURNAL in the article by Theodore S. Rosen, M.D., and George W. Lubinsky, A.B., entitled "Freezing of Tissues With 'Dry Ice' for Microtome Sectioning of the Entire Brain," the first two sentences in the paragraph under "Freezing Apparatus" should read: "The freezing attachment consists essentially of (1) a metal plate upon which the slab of tissue is frozen, and (2) a means of keeping the 'ice' *in firm contact with the metal plate. The plate is cooled by the 'ice'* and in turn chills the tissue, at the same time anchoring the tissue to the plate." The words that are italicized were omitted from the text.

DEPARTMENT OF ABSTRACTS AND REVIEWS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

PNEUMOCOCCI, Sensitivity of to Sulfapyridine, A Rapid Qualitative Test for Resistance, Moore, F. J., Thomas, R. E., and Hoyt, A. J. A. M. A. 117: 437, 1941.

Each of 4 mice was inoculated intraperitoneally with 0.2 c.c. of 10 per cent sulfapyridine suspended in 20 per cent acacia. Sputum (or pus) was made grossly homogeneous and liquid by mixing with a minimum necessary amount of sterile saline solution. Within the first two hours after treatment, 4 treated and, in addition, 3 untreated mice were alternately inoculated with the sputum mixture, as large a volume as possible (up to 1 c.c.) being used for each mouse. At various intervals thereafter peritoneal exudate was removed from each mouse and examined rapidly to determine the number and the morphology of the pneumococci. Efforts to make accurate counts were avoided. The test was read when growth of pneumococci in the untreated mice had become unquestionable (as indicated by hundreds per oil-immersion field), and at no earlier time. If, at this time, the treated mice showed no increase in the number of pneumococci, or if there had been scanty growth with a preponderance of atypical forms, the strain was called sensitive; if smears of treated and control mice were virtually indistinguishable, the strain was called resistant (fast or refractory).

TRICHINOSIS, Wyrens, R. G., Tillisch, J. H., and Magath, T. B. J. A. M. A. 117: 428, 1941.

In an analysis of 19 cases of clinical trichinosis and 21 cases of asymptomatic infection incidental diagnoses were made during routine examination of surgical pathologic material. Included in the series are 2 cases suggestive of repeated infection.

Asymptomatic infection with *T. spiralis* and clinical trichinosis are two conditions which should be clearly separated.

SPOTTED FEVER, Rocky Mountain, Hutton, J. G. J. A. M. A. 117: 413, 1941.

The literature shows that cases of Rocky Mountain spotted fever have been reported from thirty-seven of the forty-eight states.

Rocky Mountain spotted fever is transmitted to human beings through infected ticks, and the causative organism is *Dermacentoroxenus rickettsii*.

Three types of the disease are recognized: the mild, the severe, and the fulminating.

The cutaneous manifestations of Rocky Mountain spotted fever are characteristic.

A drug exerting any great amount of specific action against this infection has not been found.

Vaccine gives partial protection for a period of one year or less.

The United States Public Health Service vaccine for Rocky Mountain spotted fever is prepared at the Rocky Mountain Laboratory of the National Institute of Health at Hamilton, Mont.

The vaccine is given in two doses of 2 c.c. each at an interval of five days, either subcutaneously or intramuscularly. The known data indicate that the vaccine fully protects the majority of persons against the less virulent strains but that the average person is only partially protected against the highly fatal type of Rocky Mountain spotted fever, and that the maximum degree of protection conferred is retained for less than one year.

GNOCOCCIC INFECTIONS, Cutaneous Diagnosis of, Corbus, B. C., and Corbus, B. C., Jr.
J. A. M. A. 116: 113, 1941.

A person infected with a specific organism is in a state of hypersensitivity to that organism as long as it remains within the body.

In a control series of 100 persons known not to be infected with gonococci, 85 per cent gave negative reactions to the cutaneous test described.

According to the authors' experience, this test as a diagnostic adjunct in gonococcal infections is more valuable than any other procedure previously available.

The antigen consists of 0.1 c.c. of a standard bouillon culture filtrate with 0.1 c.c. of bouillon as a control.

COLOR INDEX, A Simple Hemoglobin-Red Cell Ratio to Replace the, Isaacs, R. J. A.
M. A. 116: 2258, 1941.

A simple relationship between the hemoglobin content of the blood and the number of red blood cells may be expressed by this formula for "normal": Three times the number of grams of hemoglobin per hundred cubic centimeters divided by the number of hundreds of thousands of red blood cells per cubic millimeter equals 1. It is distinctly less than 1 in hypochromic anemias and more than 1 in hyperchromic conditions.

URINE, Method for Rapid Alkalinization of, Bick, M., and Drevermann, E. B. M. J.
Australia 1: 223, 1941.

The authors advocate the immediate intravenous administration of 20 c.c. of the sodium lactate-sodium bicarbonate solution on the first appearance of any symptoms suggestive of the occurrence of hemolysis after blood transfusion. This is, however, only the immediate treatment, and as large quantities of fluid are required to maintain the diuresis, the purpose of the injection is to alkalinize the urine rapidly in order to permit time for the setting up of a continuous intravenous infusion of isotonic sodium lactate solution.

HEMOPHILIA, Diagnosis of, Quick, A. J. Am. J. M. Sc. 201: 469, 1941.

The blood of a true case of hemophilia should show the following:

1. Coagulation time (Lee White test), over eight minutes at 37.5° C.
2. Coagulation time of recalcified plasma:
 - a. High speed centrifugation, over five minutes.
 - b. High speed centrifugation, over three minutes.
 - c. Clotting time should decrease on standing.
3. Prothrombin concentration (Quick's method), above 70 per cent.
4. Bleeding time (Duke's method), not over four minutes.
5. Clot retraction, not over sixty minutes after coagulation occurs.
6. Tourniquet test (Rumpel-Leede technique), not over four petechia in specified area.

BLOOD DONORS, Response of, to Iron, Santy, A. C. Am. J. M. Sc. 200: 790, 1941.

The hemoglobin response of 27 active professional blood donors was studied under iron therapy and without medication.

It was found that hemoglobin regeneration after donations took place eight times more rapidly when iron was given.

The return to the previous level was complete in an average of eleven days after a 500 c.c. donation under iron therapy, whereas a far longer period was necessary when iron was withheld.

A rough calculation of the amount of hemoglobin in the total circulation revealed the fact that the average active donor in this series could not maintain a positive balance without iron medication.

It was found that the response to iron usually continued after its withdrawal, indicating that the most effective time to administer iron is before blood loss.

It is concluded that the diet of regular donors should be supplemented with iron. Ferrous sulfate, because of its convenience and freedom from reactions, was regarded as a very satisfactory form of iron for blood donors.

"STORED" BLOOD. Effect of Glucose in the Preservation of Citrated Human Blood Stored at 4-6° C., Belk, W. P., and Rosenstein, F. *Am. J. M. Sc.* 200: 841, 1941.

Glucose (5.4 per cent) prevents the hemolysis of erythrocytes of whole citrated human blood kept at 4° to 6° C. for three to four weeks. With citrate alone hemolysis appears near the end of the first week.

This preserving effect is less marked on granulocytes, platelets, and on the clot-forming properties.

One part of isotonic glucose to two parts of blood is effective, and has the advantage of increasing not too greatly the amount of fluid to be injected.

It must not be thought that blood preserved by chilling and the addition of glucose remains in a state of hibernation, or suspended animation. The processes of decay go on steadily, and are retarded only by the favorable environment. There is, therefore, a strict limit to the time that blood for transfusion may properly be stored. This limit is shorter than is generally supposed due to the fact that these red blood cells become incapable of substituting for the cells of the recipient prior to suffering any hemolysis.

"STORED" BLOOD: Survival Time of Erythrocytes of Citrated Human Blood Stored at 4-6° C., Belk, W. P., and Barnes, B. C. *Am. J. M. Sc.* 200: 838, 1941.

The erythrocytes of citrated human blood kept at 4° to 6° C. were found to survive in recipients as long as the cells of fresh blood when storage time did not exceed two or three days. After this they disappeared with increasing rapidity as storage time increased, until, after seven or more days in the "bank" their post transfusion survival was in no case longer than twenty-four or forty-eight hours.

GONOCOCCUS, Preservation of, in Frozen Urines and Broth, Wortman, M. S., Gronau, A., Deakin, R., and Love, F. *Ven. Dis. Inform.* 22: 195, 1941.

Routine Method:

The urethral discharge of male patients with gonorrhea was collected on a sterile swab which was then immersed in a serologic tube containing 1.5 c.c. of infusion broth. Subsequently the specimen was plated out on a chocolate agar plate. If there was no discharge, the first portion of the urine was collected in a sterile centrifuge tube. The sediment was taken up on a swab after centrifugation and transferred into a broth tube. A culture was then made as stated above.

In female patients the cervix was exposed by means of a speculum, avoiding the use of lubricants. A specimen was taken from the urethra and cervix with a swab which was then immersed in a broth tube and later plated out as described.

Freezing Method:

(A) *Broths.* A routine culture was made from the discharge in both male and female patients, and the swab was then placed back into the broth tube. The broth tube was immersed in the freezing mixture of dry ice and alcohol (temperature about -72° C.). Freezing occurred in about fifteen to twenty seconds. The specimens were transferred when frozen to a thermos bottle containing dry ice.

(B) *Urines.* Urines collected in sterile 15 c.c. centrifuge tubes were frozen by immersing the tubes in the freezing mixture. Freezing occurred in about one and one-half to two minutes. The tubes were transferred after freezing to a thermos bottle containing dry ice.

TUBERCLE BACILLI, Demonstration of, Sasano, K. T., Caldwell, D. E., Needham, E. L., and Medlar, E. M. *Am. Rev. Tuberc.* 43: 263, 1941.

A comparison of results obtained from culturing and inoculating guinea pigs for the detection of tubercle bacilli in 1,270 specimens from human sources is presented. The results obtained from culturing the spleens from 100 consecutive tuberculous guinea pigs, using the technique briefly outlined in the text, are given. The advantages and disadvantages of each method are discussed. To substitute the cultural method for the guinea pig inoculation procedure seems inadvisable. The utilization of both methods counterbalances certain inherent disadvantages in each. As a routine procedure a combination of the two methods will make possible a more accurate detection of tubercle bacilli present in small numbers than is possible where only one or the other method is used.

TUBERCLE BACILLI, Culture of, Steenken, W., Jr., and Smith, M. M. *Am. Rev. Tuberc.* 43: 309, 1941.

A fifty-hour sputum specimen is collected in a 100 c.c. wide-mouthed bottle, stoppered with a good grade of cork. An equal volume of 4 per cent sodium hydroxide is added, and the mixture is homogenized for ten minutes in a shaking machine, followed by one hour's incubation at 37.5° C. It is then centrifuged for ten minutes at high speed in sterile pyrex tubes which have been sealed with sterile rubber caps (type used for capping babies' milk bottles). The sediment is neutralized with normal hydrochloric acid containing 10 per cent by volume of phenol red indicator, and adjusted on the acid side to a pH of about 6.4 (it is best to approach the final pH with either N/10 hydrochloric acid or N/10 sodium hydroxide as may be required).

This suspended sediment is divided into three equal portions. Two of these portions are transferred to two small vials with round bottoms that will stand centrifuging and which can be stoppered with small corks. (Small round bottom 5 c.c. vaccine vials are well suited for this purpose.) To one vial, 5 c.c. of a 1:1,000 solution of malachite green is added, and to the other vial, 5 c.c. of a 1:10,000 solution. The third vial is kept as a control. The vials which contain the dye are then stoppered and agitated in the shaking machine for ten minutes, then centrifuged for ten minutes at high speed. The supernatant fluid is pipetted off with a sterile capillary pipette. The sediment is then suspended in 1 c.c. of sterile distilled water.

STREPTOCOCCI, Comparison of Beta-Hemolytic on Maltose-Blood-Agar. A Presumptive Test for Group A, Simmons, R. T., and Wilson, H. M. *J. Australia* 1: 74, 1941.

A total of 869 strains of beta hemolytic streptococci of human origin of groups A, B, C, and G were examined on maltose-blood-agar plates as a presumptive means of distinguishing strains of group A from the other three groups, which are commonly found in man but are rarely pathogenic to man.

Of 500 strains of group A streptococci, all but four (0.8 per cent) were recognized. Of 369 strains of groups B, C, and G, all but 15 (4 per cent) were recognized as not of group A.

As a presumptive test for group A streptococci, the medium maltose-blood-agar was useful, and, with few exceptions, reliable. As a presumptive test for group B among hemolytic streptococci of human origin, it was quite reliable. Groups C and G were not distinguishable from one another, but most strains of groups C and G were distinguishable from group A, and all strains were distinguishable from group B.

CLINICAL AND EXPERIMENTAL

AMPHETAMINE SULFATE-ETHYL ALCOHOL ANTAGONISM IN THE RABBIT*

EDWARD C. REIFENSTEIN, JR., M.D., SYRACUSE, N. Y.

DURING an investigation in man of the stimulating action of amphetamine (benzedrine) sulfate on abnormal mental states characterized by depression, certain toxic depressive states caused by alcohol were included, and it was observed that the alcoholic cases were among those most favorably affected.¹⁻⁴ These observations indicated that in man there is an antagonism between amphetamine sulfate and ethyl alcohol.

In a series of over 100 cases of alcoholism, with and without psychosis, our most prominent results of treatment included: (1) a reduction by one-half in the length of time for recovery of the acute alcoholic psychoses; (2) a slight increase in the number of recoveries; (3) a diminution in the severity of the psychotic manifestations; (4) a dissipation of the "hang-over" effects of inebriation; (5) an unsatisfactory response in chronic alcoholic addiction; (6) a differentiation between uncomplicated alcoholic depressions and psychogenic depressions masked with alcohol by the rapid response of the former; and (7) an antagonistic or "sobering" effect of amphetamine during acute alcoholic intoxication. The latter was most striking. Boisterous, excited, hyperactive, surly and irritable individuals became quieted; some fell asleep after the medication. Tremor in these patients was aborted. Occasionally, however, the excitement and the tremulousness was increased. The incoherence and incoordination of more profound inebriation was rapidly replaced by a more coordinate state. Persons who had imbibed sufficiently to become stuporous frequently were aroused and rational within thirty minutes following the intravenous injection

*From the Departments of Pharmacology, Medicine and Psychiatry, College of Medicine, Syracuse University.

Aided by a grant from Smith, Kline and French Laboratories, Philadelphia, Pa.

Received for publication, September 25, 1940.

of 20 to 30 mg. of amphetamine sulfate. The drug rendered depressed, sullen, and asocial intoxicated individuals more cheerful and adaptable. Some chronic alcoholic patients took amphetamine before drinking in order to consume larger quantities of alcohol without the appearance of unpleasant symptoms. We concluded from these investigations that in man there is an antagonism between amphetamine sulfate and alcohol, which is of greatest value clinically in the more acute phases of alcoholism with and without psychosis.

PRESENT INVESTIGATION

Because of the satisfactory response of acutely alcoholic patients to amphetamine sulfate, it seemed desirable to test in animals the limits of the antagonism between the two drugs. Since this investigation was begun (October, 1938), Werner⁵ has published a brief report on the effects of amphetamine sulfate on alcoholic depression in animals. He stated that 7 c.c. per kilogram of alcohol orally protected rabbits against the lethal effects of subsequently administered amphetamine sulfate. The lethal dose of amphetamine was increased approximately 1.5 times. The drug did not completely awaken the depressed animals. However, in rabbits receiving 2.5 c.c. per kilogram of alcohol intravenously, coordination of the hind legs was restored by amphetamine. Entirely similar results were obtained by Werner with pyridine-B-carboxylic acid diethylamide (coramine), metrazol, and picrotoxin.

MATERIALS AND METHODS

Inasmuch as both the alcohol and the amphetamine sulfate had been administered orally in the clinical studies, it was decided to administer the drugs to animals by the same route. The rabbit was used because of suitable size for ease in passing a stomach tube. From a colony of about 800 rabbits, approximately 600 were chosen at random and employed in the present investigation. These animals were equally distributed in sex, and varied in age from 6 to 15 months, and in weight from 1.50 to 3.20 kg. Subsequently, the experimental group was reduced to 423 by eliminating from the data those rabbits weighing less than 1.70 or more than 3.00 kg., because of the observation of Ehrlich, Lewy, and Krumbhaar⁶ that the minimum lethal dose varied with the weight (age) of the animals and that the heavier animals were more susceptible. However, in no instance were the results modified by thus restricting the number of animals. No seasonal variation in the susceptibility of the animals to the same mixture of the drugs was observed. In many instances the solutions containing different mixtures were employed simultaneously, thus rendering the variations in response more easily comparable.

All animals were fed on a standard laboratory diet, which had maintained in good health for several years the remaining 200 rabbits (employed in pregnancy tests). In every experiment food was withheld routinely for more than sixteen hours before and after medication. No animal was used more than once throughout the investigation. All medications were administered intragastrically as solution, using an 18 F urethral catheter as an esophageal tube. Preliminary experiments indicated that the average stomach capacity of the selected animals was 150 to 250 c.c. All solutions were devised, therefore, so

that the total volume of a single dose never exceeded 150 to 175 c.c. (depending on the size of the animal). All solutions were made, however, so that the volume administered would be as large as possible, in order to minimize drug loss and in order to eliminate the necessity of washing down a given dose with additional fluid and thus changing the concentration. To secure uniform freshness, the solutions were prepared as needed. The amphetamine sulfate used was the racemic compound, in the form of a powder,* dissolved in distilled water. The alcohol solutions were prepared from alcohol U.S.P. (i.e., 95 per cent).

The particular techniques are described in connection with the divisions of the problem. In the lethal dose experiments the dose was considered to be fatal only if the animal died within fourteen days of medication. The term "minimum lethal dose₅₀ (M.L.D. 50)" is used to describe that dose which was lethal to at least 50 per cent of the animals to whom it was given.

Average	17.4	408		55.9	307

RESULTS

A. Moderate Dose Experiments.—The following experiments were performed to determine the effect of amphetamine sulfate on the narcosis of moderate amounts of ethyl alcohol (Table I):

(1) To a series of 13 animals (control group), 5 Gm. per kilogram of alcohol were administered intragastrically. The onset and the duration of narcosis were recorded. The animals were stimulated at five- to ten-minute intervals by a forceful pinching of the ear with a mouse-toothed forceps, and were not considered to be in a state of narcosis if they could coordinate their hind legs sufficiently to hop once without losing balance. Narcosis occurred in 17.4 minutes (average) after the administration of the alcohol, and lasted 408 minutes (average).

*Racemic amphetamine sulfate powder was supplied through the courtesy of Mr. Theodore B. Wallace, Smith, Kline and French Laboratories, Philadelphia, Pa.

(2) The same experiment was performed in another series of 13 animals (test group) to whom 5 Gm. per kilogram of alcohol and 85 mg. per kilogram of amphetamine sulfate were given in the usual manner. Sleep ensued in 55.9 minutes (average) and lasted 307 minutes (average).

Comparison reveals that the addition of the amphetamine sulfate delayed the onset of the narcosis about 200 per cent, and shortened it about 25 per cent.

Fig. 1.

Statistical Treatment of Results: Onset of narcosis—the standard error of the mean of the control group was 1.786 minutes and of the test group, 4.94 minutes. The ratio of the difference of the means to the standard error of their difference was 1.857, indicating but thirty-two chances in one thousand of a reversal in similar experiments. *Duration of narcosis*—the standard error of the mean of the control group was 7.869 minutes and of the test group, 12.9 minutes. The ratio of the difference of the means to the standard error of their difference was 11.5, indicating an infinitesimal chance that there would be a reversal in similar experiments. The degree of significance of the changes of the onset and the duration of the narcosis is increased by the fact that amphetamine sulfate altered both of these factors in the same direction.

B. Lethal Dose Experiments.—Five experiments were performed to determine the effect of amphetamine sulfate on lethal doses of ethyl alcohol, and the effect of ethyl alcohol on lethal doses of amphetamine sulfate:

(1) *M.L.D. 50 of Ethyl Alcohol:* Varying doses of 25 per cent ethyl alcohol solution were given to 38 animals, and the number of deaths within fourteen days was recorded. The volume of the solution administered varied from 58 to 112 c.c. The M.L.D. 50 was found to be 7.25 Gm. of alcohol per kilogram (Fig. 1).

(2) *M.L.D. 50 of Amphetamine Sulfate:* In a manner similar to the preceding experiment, 0.25 per cent solution of amphetamine sulfate was given to 68 animals. The volume of the solution administered varied from 44 to 130 c.c. The M.L.D. 50 was found to be 85 mg. per kilogram (Fig. 2).

(3) *M.L.D.₅₀ of Mixture A*: Mixture A (7.25 Gm. of ethyl alcohol (1 *M.L.D.₅₀*) and 42.5 mg. of amphetamine sulfate ($\frac{1}{2}$ *M.L.D.₅₀*) in 37 c.c.) contained alcohol and amphetamine in approximately 25 per cent and 0.15 per

Fig. 2.

Fig. 3.

cent concentration, respectively. Varying quantities of this mixture were administered to rabbits, and the number of deaths within fourteen days was tabulated. The amounts of ethyl alcohol per kilogram and amphetamine sulfate per kilogram for a given quantity of mixture A solution were then calculated.

The volume administered varied from 45 to 115 c.c. A series of 63 animals was required. The M.L.D.₅₀ of the mixture A solution was found to contain 6.025 Gm. per kilogram of ethyl alcohol and 35.32 mg. per kilogram of amphetamine sulfate (Fig. 3).

(4) *M.L.D.₅₀ of Mixture B*: The procedure was the same as the preceding one. Mixture B (7.25 Gm. of ethyl alcohol (1 M.L.D.₅₀) and 85 mg. of amphetamine sulfate (1 M.L.D.₅₀) in 37 c.c.) contained alcohol in approximately 25 per cent solution, and amphetamine in approximately 0.3 per cent solution. A volume of solution varying from 47 to 102 c.c. was given to 55 animals. The M.L.D.₅₀ of the mixture B contained 5.78 Gm. per kilogram of ethyl alcohol and 67.72 mg. per kilogram of amphetamine sulfate (Fig. 4).

Fig. 4.

(5) *M.L.D.₅₀ of Mixture C*: The same technique was employed. Mixture C (3.625 Gm. of ethyl alcohol ($\frac{1}{2}$ M.L.D.₅₀) and 85 mg. of amphetamine sulfate (1 M.L.D.₅₀) in 34 c.c.) contained alcohol in approximately 16 per cent solution, and amphetamine in approximately 0.25 per cent solution. A volume of solution varying from 62 to 175 c.c. was administered to 99 animals. The M.L.D.₅₀ of the mixture C solution was found to contain 5.239 to 5.968 Gm. per kilogram of ethyl alcohol and 125 to 140 mg. per kilogram of amphetamine sulfate (Fig. 5). It should be noted that even in this large series of animals, there was so much individual variation that an exact single value for the M.L.D.₅₀ could not be determined. Inasmuch as the range of values obtained was satisfactory to indicate the trend, the experiments were terminated.

ANALYSIS OF RESULTS AND DISCUSSION

The results of animal experimentation cannot be strictly applied to man. However, in the experiments herein recorded, amphetamine sulfate has exhibited

in antagonistic effect in rabbits intoxicated with moderate quantities of alcohol, and this seems to confirm the clinical observations previously cited of the effectiveness of amphetamine sulfate in acute alcoholic states in man.

Fig. 5.

Fig. 6.

In the lethal dose experiments, however, the addition of amphetamine sulfate up to 1.5 times the minimum lethal quantity had no effect in protecting the rabbits from the M.L.D.50 or more of alcohol. Indeed, the presence of the

amphetamine increased the toxicity so that the animals tolerated less alcohol (Fig. 6). This suggests a clinical danger which is more apparent than real. In acute alcoholic states in man there is present a quantity of alcohol, which rarely, if ever, approaches a lethal amount, because the hypnotic action of alcohol usually manifests itself long before a lethal quantity can be consumed. In these clinical conditions, therefore, the use of amphetamine sulfate is not likely to be attended with the danger of producing increased toxicity.

In contrast to these findings, alcohol up to 80 per cent of a lethal quantity protected the rabbits from 1.5 times the minimum lethal dose of amphetamine sulfate. This increased protection has been confirmed by Werner,⁵ previously cited. Because of the widespread employment of amphetamine sulfate in various disease conditions, the possibility of using alcohol as an antidote in states of acute amphetamine poisoning should be kept in mind.

The possibility that these manifestations are due to disturbances in absorption must be considered. However, if the amphetamine interfered with the absorption of the alcohol, there should be an increased protection against alcohol when large doses of alcohol and small doses of amphetamine are used together, instead of an increased toxicity. Likewise, even if the alcohol interfered with the absorption of amphetamine, this would not explain the occurrence of the increased toxicity to alcohol when large doses of alcohol and small doses of amphetamine are employed together.

SUMMARY

Four hundred twenty-three rabbits were selected as to age (6 to 15 months), weight (1.70 to 3.00 kg.), sex (equal numbers), and given solutions of amphetamine sulfate and/or ethyl alcohol by stomach tube. The standard laboratory diet was withheld for over sixteen hours before and after administration.

The following data were obtained:

(1) The administration of 5 Gm. per kilogram of alcohol to 13 animals produced narcosis (inability after painful stimulus to hop once without losing balance) with an onset of 17.4 minutes and a duration of 408 minutes (average). (2) The administration of 5 Gm. per kilogram of alcohol with 1 M.L.D.₅₀ (85 mg.) of amphetamine per kilogram to another 13 animals produced narcosis with an onset of 55.9 minutes and a duration of 307 minutes (average). The addition of amphetamine delayed the onset of the narcosis about 200 per cent and shortened it about 25 per cent.

(3) The M.L.D.₅₀ of 25 per cent alcohol (38 animals) was 7.25 Gm. per kilogram. (4) The M.L.D.₅₀ of 25 per cent amphetamine (68 animals) was 85 mg. per kilogram. (5) The M.L.D.₅₀ of mixture A (1 M.L.D.₅₀ of alcohol and $\frac{1}{2}$ M.L.D.₅₀ of amphetamine per unit volume) (63 animals) was 6.025 Gm. per kilogram of alcohol with 35.32 mg. per kilogram of amphetamine. (6) The M.L.D.₅₀ of mixture B (1 M.L.D.₅₀ of alcohol and 1 M.L.D.₅₀ of amphetamine per unit volume) (55 animals) was 5.78 Gm. per kilogram of alcohol with 67.72 mg. per kilogram of amphetamine. (7) The M.L.D.₅₀ of mixture C ($\frac{1}{2}$ M.L.D.₅₀ of alcohol and 1 M.L.D.₅₀ of amphetamine per unit volume) (99 animals) was 125 to 140 mg. per kilogram of amphetamine with 5.329 to 5.968 Gm. per kilogram of alcohol.

CONCLUSIONS

In the rabbit (1) amphetamine sulfate has an antagonistic effect on the narcosis of moderate amounts of ethyl alcohol. (2) It does not have an antagonistic action on the narcosis of lethal doses, and even increases the toxicity of near-lethal quantities. (3) Ethyl alcohol, on the contrary, protects the animal from 1.5 to 2 times the M.L.D.₅₀ of amphetamine sulfate.

In man these findings may be correlated with the antagonistic effect of amphetamine sulfate in acute alcoholic states. Inasmuch as such conditions involve only moderate quantities of alcohol, and rarely, if ever, near-lethal amounts, the possibility of increased toxicity from the amphetamine sulfate-ethyl alcohol combination is remote.

Alcohol may be of value as an antidote in states of acute amphetamine poisoning.

Grateful acknowledgment is made to Dr. M. S. Dooley for advice and criticism, to Dr. H. P. Smith for statistical analyses of the results, and to Dr. John Rowlingson for technical assistance.

1801 STATE TOWER BUILDING

TOXIC REACTIONS TO SULFAPYRIDINE*

ACUTE HEMOLYTIC ANEMIA, LEUCEMOID REACTION, AND PURPURA IN
THREE SEPARATE CASES

A. ALLEN GOLDBLOOM, M.D., F.A.C.P., LOUIS GREENWALD, M.D., AND
H. REINSTEIN, M.D., NEW YORK, N. Y.

SULFAPYRIDINE, like most other potent chemotherapeutic agents, has concomitant side effects and toxic reactions. A knowledge of these facts cannot be too strongly stressed for the safe administration of the drug. The deleterious effect of sulfapyridine on hemopoiesis of susceptible individuals is among the most dangerous of its toxic actions. Several cases¹⁻⁶ of bone marrow depression, as evidenced by leucopenia with agranulocytosis or thrombocytopenia, have been reported from large or even small doses of the drug. This is not surprising, since the benzene ring is present in sulfapyridine and is capable of causing blood

*From the Medical Services, Metropolitan and Flower-Fifth Avenue Hospitals, New York City, Dr. Linn J. Boyd, Medical Director.

Received for publication, September 26, 1940.

reactions affecting the formed elements of the blood either singly or in combination, producing acute hemolytic anemia, unusual leucocytosis, or leucemoid blood pictures, leucopenia with malignant neutropenia, or agranulocytosis and thrombocytopenia with hemorrhagic phenomena.

To date, there has been only one report⁷ of leucemoid reaction due to inordinate stimulation of the bone marrow by sulfapyridine. It is, therefore, felt worth while to describe three additional cases of serious bone marrow damage caused by this drug, which produced this leucemoid blood picture in addition to severe hemolytic anemia in the first two patients, and thrombocytopenic purpura in the third patient.

CASE REPORTS

CASE 1.—F. C. (No. 105350), a 25-year-old male was admitted on Dec. 25, 1939, and discharged on Jan. 14, 1940. He complained of fever, chills, cough with expectoration of greenish, blood-stained sputum, and pain in the right chest for six days before admission. Physical examination revealed an acutely ill colored male with tachypnea, widened alae nasi, dullness of right upper chest anteriorly, where bronchovesicular breathing and crackling râles were heard. The clinical diagnosis of pneumonia of the right upper lobe was corroborated by x-ray taken the day of admission.

The urine, blood glucose, and nonprotein nitrogen on admission were normal. The Wassermann test was negative.

The patient was given 30 grains of sulfapyridine on admission (Dec. 25, 1939) and 15 grains every four hours until Jan. 1, 1940. The temperature, which was 102° F. on admission, dropped to 99° F. by December 27, and stayed at a normal level until December 31, when it rose to 101° F. for four days. The secondary rise in temperature on December 31, was due to the action of the drug causing a severe hemolytic anemia (Table I) and not to the pneumonic process which showed complete resolution both by physical signs and x-ray on Jan. 1, 1940.

It will be noted that the hemoglobin of 95 per cent on admission fell to 60 per cent after four days of the administration of sulfapyridine, and the red blood cells fell from 4.5 to 3 million. There was a marked leucocytosis (31,000) with the appearance of many premature forms in the circulating blood. By Jan. 1, 1940, the red blood cells had fallen to exceedingly low proportions: the hemoglobin fell to 20 per cent with 1.5 million red blood cells. The white blood count rose to 64,800. The patient now exhibited an icteric tinge of the skin. The icteric index was 10; the van den Bergh was positive and delayed; urobilin excretion was increased in the urine at this time; wet preparation for sickling of erythrocytes was negative. The sulfapyridine was immediately discontinued, and a blood transfusion was given on the same day; this was repeated two days later. A bone marrow puncture revealed a hyperactive erythronormoblastic marrow (Table I). When the temperature fell to normal on January 4, the blood rapidly returned to normal, and by January 8 no abnormal elements were seen in the blood. The patient's clinical condition improved rapidly and he was discharged, fully recovered, on Jan. 14, 1940.

The marked acute hemolytic anemia and the marked response of the granulocytic cells with many immature forms produced a leucemoid blood picture in this case, which lasted only a few days and responded to blood transfusion after discontinuance of sulfapyridine.

CASE 2.—J. T. (No. 106133), a 49-year-old male, was admitted on Jan. 17, 1940, and discharged on Feb. 11, 1940. The patient complained of pain in the left chest, with fever, cough, and expectoration of thick sputum for four days.

Physical examination revealed an acutely ill patient with a temperature of 103° F. There were absolute dullness, bronchophony, bronchial breathing, and crackling râles at the left base of the lung. The clinical diagnosis of left lower lobe pneumonia was corroborated by x-ray on Jan. 17, 1940.

The patient was given 30 grains of sulfapyridine on admission. This was repeated four hours later, and then 15 grains were given every four hours. On January 21 and 22, icterus developed. The blood count (Table II) showed rapidly developing anemia. The sulfapy-

ridine was discontinued on January 22, and blood transfusion was given. This was repeated on January 24 and January 28. As the blood chart shows (Table II), there was a milder leucemoid reaction in this case than in the former one (Table I), the height of the leucocyte rise being only 28,750. Numerous abnormal cells were found in the circulating blood. The hemolytic process also seemed milder than in the first case. Sickling in wet preparations was negative. The bone marrow in this patient (Table II) was similar to the previous case and showed a hyperplastic erythronormoblastic tendency. When the patient was discharged, he had fully recovered from the toxic effects of sulfapyridine on the blood.

CASE 3.—M. K., a 50-year-old female, was admitted on Nov. 23, 1939, and discharged on Jan. 7, 1940. Her illness began on November 18, with pain in the chest, cough, chill, and blood-tinged sputum. A diagnosis of pneumonia was made prior to admission and about 60 grains of sulfapyridine were administered daily. She entered the hospital because of the increase in chest pain and rise in temperature.

Physical examination revealed marked dullness, increased tactile and vocal fremitus, and fine crepitant râles over the right middle and lower lobes. The clinical diagnosis of pneumonia was substantiated by x-ray on November 24, showing clouding in the right side, with suggestion of some interlobar pleural thickening.

The admission temperature was 103° F. Maintenance doses of sulfapyridine (90 grains in all) were administered. The temperature declined to 98° F. on the third day, when bright red blood was expectorated. Two hemorrhagic papillomatous masses were observed on either side of the buccal mucous membrane near Stensen's duct. There were elevated red papillae at the borders of the tongue and hemorrhage in the gingival tissue of the lower jaw. In addition, there was moderate vaginal bleeding. That night a generalized rash was noticed, with hemorrhagic papillomatous masses throughout the buccal mucous membrane. There was also hemorrhage into the left sclera. The sulfapyridine was discontinued, and a blood transfusion was given with 500 c.c. of saline and coagamine (thromboplastin). The following day the patient showed marked pallor. Purpura appeared in scattered patches over the trunk and extremities, as well as a large ecchymotic area over the left thigh. This constituted the height of the toxic reaction. With transfusion, coagamine, and time the patient recovered and was discharged well, except for some chronic pneumonitis and pleural thickening as a residue of her pneumonia.

As a study of the blood shows (Table III), this patient entered the hospital with an anemia (54 per cent hemoglobin, 3,500,000 red blood cells), undoubtedly due to the administration of sulfapyridine. The anemia alone was not considered sufficiently profound to withhold sulfapyridine because of the clinical picture of the patient. The purpuric manifestations which developed on the fourth day were of the secondary type of thrombocytopenic purpura, with low platelet count (25,000), prolonged bleeding time (twenty-five minutes), and delayed clot retraction time. The leucemoid reaction in this patient (35,000 W.B.C. with 12 per cent neutrophilic myelocytes) was less marked than in the first case, but still forms an important part of this patient's toxic reaction to sulfapyridine. The bone marrow study here was not significant, because it was taken after transfusion, and it failed to show depression or hyperactivity (Table III).

DISCUSSION

Although the two drugs sulfanilamide and sulfapyridine are closely related, and their toxic effects are quite similar, this discussion is concerned with the latter drug, and shall be limited to its toxic action on the blood. This is probably the most important toxic effect of sulfapyridine, since it occurs not infrequently, is usually severe, and occasionally is fatal. Some degree of anemia is reported in fully 3 per cent of 3,000 cases that received sulfapyridine.⁸ The anemia produced by the drug is of the acute hemolytic type, usually occurs during the first three or four days of therapy with rapid hemolysis of the red blood cells, and a rise in serum bilirubin. There is a rapid decline in hemoglobin and red blood cells to alarmingly low levels of 20 per cent, and even

to one million red blood cells with all the findings of an acute hemolytic crisis, with the presence of frequent normoblasts, anisocytosis, poikilocytosis, frequent macrocytosis, hyperchromia, polychromatophilia, basophilic stippling, and reticulocytosis (Fig. 1). The peak of the reticulocytosis occurs at the third or fourth day; in Case 1, to a rise of 25.6 per cent, and in Case 2, to 13.4 per cent. The action of the drug appears to be entirely peripheral, because the few bone marrow studies, including our own, which have been made in these cases, show no depression but rather hyperplasia and increased hematopoietic activity of the marrow. The bone marrow in the first two cases (Tables I, II) showed great cellularity and hyperplasia, especially of the erythropoietic elements, such as an increase in erythroblasts, with normoblasts and occasional megaloblasts (Figs. 2 and 3). This hyperplasia is undoubtedly due to an attempt on the part of

Fig. 1.—Showing reticulocytosis.

the bone marrow to compensate for the rapid intravascular blood destruction in an effort to meet the increasing demands for regeneration in order to combat the anemia. The myeloid elements show a moderate degree of hyperplasia with a shift to the left. Although the hemolysis and anemia are somewhat progressive even after the withdrawal of sulfapyridine, the anemia usually improves with repeated blood transfusions. It is of interest to note that, with clinical improvement showing an increase in hemoglobin and red blood cells, the bone marrow shows a corresponding reduction in erythroid cells.

Since there is no abnormal fragility of the red blood cells in these cases, it may be assumed that they are destroyed directly by some hemolytic process or indirectly through the reticulo-endothelial system. It is known that the effect of sulfapyridine on the blood is often selective, causing hemolytic anemia with moderate leucocytosis. As with sulfanilamide, the most commonly reported damage caused by sulfapyridine is marked reduction of the number of leucocytes with granulocytopenia.⁴ The mechanism is probably on a basis of maturation

arrest or hypoplasia of the granulocytic series in the bone marrow, similar to that seen following benzol, aminopyrine, etc. There has been only one report to date of the opposite toxic effects producing a leucemoid picture. Leucemoid reactions have been reported by Heck and Hall⁹ and have been observed in overwhelming infections more commonly of coccal than bacillary origin, sepsis, uremia, occasional heavy metal poisons, measles, infectious mononucleosis, hemolytic anemia, polycythemia vera, instances of the lymphomatous diseases, Albers-Schönberg disease, and multiple myeloma. The leucocytosis observed resulting from sulfanilamide or sulfapyridine may be due to actual irritation of the bone marrow rather than to the underlying infection, because it often occurs when

Fig. 2.

Fig. 2.—Peripheral blood smear showing marked leucocytosis with few myelocytes and normoblasts.

Fig. 3.

Fig. 3.—Hyperplastic erythronormoblastic bone marrow showing numerous erythroblasts, normoblasts, and myeloid elements.

the infection is on the decline. A diagnosis of leucemia is sometimes ventured, but the presence of a potent producing cause, the dramatic clinical improvement of the patient, and the rapid return of the blood to normal should offer no difficulties in excluding leucosis. The case reported by Moody and Knouf⁷ is similar to those reported here, showing the rather common acute hemolytic anemia and the very uncommon leucemoid reaction which responds satisfactorily after blood transfusion.

The occurrence of secondary thrombocytopenic purpura with a mild leucemoid reaction, reported in our third case, raises the question of the possible allergic reaction of sulfapyridine on the blood. According to the allergic theory,¹⁰ drugs like sulfanilamide and sulfapyridine produce thrombocytopenic purpura by sequestration or destruction of platelets caused by widespread alteration of the reticulo-endothelial system in persons who have a constitutional predisposition with acquired sensitivity to certain drugs. Although the theory cannot be easily disproved, Hodes and associates³ offer good evidence that so far as the leucopenia is concerned, the specific hematologic reaction patterns

are not due to acquired sensitivity, because patients who developed leucopenia in their first course of treatment with sulfapyridine failed to show similar reaction during their second course of treatment.

It must be admitted that as yet the exact mechanism in which sulfapyridine affects the blood and blood-forming organs adversely is not known. Nevertheless, we cannot help feeling strongly that a complete blood count should be done to determine the condition of the patient's blood before administration of the drug. Repeated blood counts either daily or at least every other day must be done so that toxic effects on the hemoglobin, red blood cells, leucocytes, and platelets may be readily detected, the drug discontinued in time, and repeated blood transfusion administered to avoid fatal outcome in these unfortunate cases.

CONCLUSIONS

Unusual toxic reactions of the blood to sulfapyridine are reported in three cases with acute hemolytic anemia, and varying grades of leucemoid blood pictures and associated secondary thrombocytopenic purpura. In spite of these serious reactions all the cases recovered in a short time after transfusions. Bone marrow studies showed erythroblastic hyperactivity in the two cases. The theories of the effects of the drug on hemopoiesis are discussed. It is believed that the marked hemolytic anemia may be evidence of a peripheral action; the leucocytosis an irritation of the myeloid element of the bone marrow; and the thrombocytopenic purpura an allergic phenomenon. The importance of frequent blood counts on any patient receiving sulfapyridine cannot be overemphasized.

We wish to thank Professor Linn J. Boyd for the privilege of reporting these cases.

PLEURAL SHOCK—A REFLEX*

PRELIMINARY REPORT

WALTER L. MERSHEIMER, M.D., AND MALCOLM L. COLMER, M.D.
NEW YORK, N. Y.

FOR many years the etiology of pleural shock has been debated; men of eminence have suggested that the cause is air embolus, while others of equal importance believe the condition is reflex in origin.

Studies have been made in which blood pressure, pulse rate, and respiration have been carefully checked. These merely serve to confirm the existence of pleural shock, but do not demonstrate its etiology.

It has been the custom here in the surgical laboratory to sacrifice animals by injecting ether into the chest cavity. Almost immediately after the injection the animal has a mild convulsion, rolls on its back, and within two or three minutes is dead, respirations having become rapid and shallow, and finally ceasing; heart action also stopping after what seems like a short period of increase in activity. Pupils become dilated; cyanosis is marked.

It occurred to us that the time elapsed was too short to account for the death on other than a reflex basis, and that the ether could not have caused an anesthetic death in so short a time. We postulated a vagovagal reflex (pleuro-cardiac) and consulted the literature for support. The reflex was suggested as early as 1865 and has been tentatively confirmed by experimental work in which atropine prevented or diminished signs of pleural shock, as did vagotomy.

We, therefore, sacrificed several rabbits left from other work by injecting ether in the pleural cavity, and taking electrocardiograms throughout the procedure. We have succeeded in killing rabbits with as little as 0.5 c.c. of ether in as little as one minute. Autopsies have revealed no gross evidence of air embolism.

Manometer readings are taken to show that the ether has been injected into the pleural cavity. Pressure increases are relatively small, showing that cardiac embarrassment due to mediastinal shift is not responsible for the deaths.

Electrocardiographic tracings are taken in all three limb leads before insertion of needle into chest. Lead II is then taken after insertion of needle and during injection of ether, and until after clinical death is evident. The records show changes in the T-wave, inversion and flattening being pronounced, and the take-off high.

*From the Graduate School, New York Medical College, Flower and Fifth Avenue Hospitals; and Metropolitan Hospital, Division of Surgery, New York City.
Received for publication, September 27, 1940.

We expect to continue this work on rabbits and larger laboratory animals. Tracings will also be made on human beings whose chests are entered for thoracentesis, pneumothorax, and surgery.

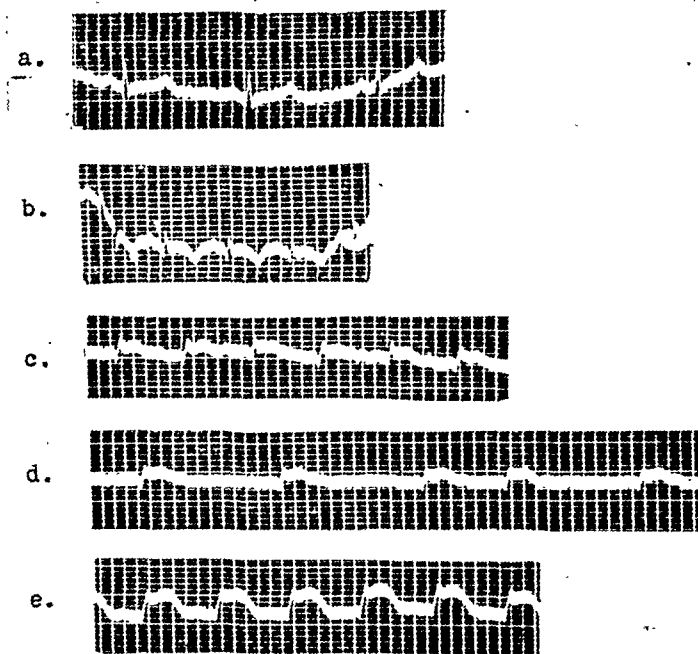

Fig. 1.—*a.* Normal electrocardiogram of a rabbit; P-waves are positive. Initial complex shows low R-wave neither split nor widened. S-T segment is in isoelectric line. T-waves are positive. *b.* Taken 67 seconds after injection, shows tachycardia, short Q-wave. R-wave is lower, T-wave is inverted. *c.* Taken 80 seconds after injection, shows high take-off of S-T segment and T-wave from the descending part of R-wave. *d.* Taken 89 seconds after injection, shows arrhythmia. P-waves are not distinctly visible. Ventricular complex is unaltered. *e.* Taken 131 seconds after injection, shows regular tachycardia with marked high take-off, causing almost a monophasic electrocardiograph.

This report is submitted so that others, dealing mainly with chest pathology and with opportunity to apply this investigation to human beings, may check our early impressions with actual clinical experience.

ENDOCRINE ASPECTS OF HEADACHES

MAX A. GOLDZIEHER, M.D., NEW YORK, N. Y.

THE problem of headaches has been investigated from several viewpoints in accordance with the fact that pain may be caused by a variety of pathologic processes affecting the structures of the head, as well as by a variety of systemic conditions, both infectious and metabolic. Headaches also develop in the absence of all organic disease as an expression of disturbances in the emotional sphere or of a psychoneurotic state. However, those either of the migraine, or a less specific type, frequently occur in patients who do not present any, or not enough, organic pathology to account for their complaints; nor can the headaches be blamed on nervous or mental conditions.

The occurrence of headaches in patients who consult the endocrinologist for varied reasons is so common that it seemed justified to investigate the possible causal relationship between endocrinopathies and attendant metabolic disorders on the one hand, and the attacks of headaches on the other.

A series of 50 consecutive cases of severe headaches is presented, most of which were of the characteristic migraine type. All cases, including those clinically not classified as migraine, were noteworthy for their severity, frequency, and refractoriness to ordinary palliative treatment. Organic pathology or systemic disease as the cause of these headaches could be ruled out by thorough clinical examination.

Oliguria was a distinct feature, for the twenty-four-hour urine output was less than 1,000 c.c. in the majority of these cases. The daily urinary volume was above that figure in one-third of the group, with a maximum of 1,780 c.c. in one patient; but all these patients admitted an increased liquid intake. The twenty-four-hour urine specimens showed an average sodium chloride content of only 6.7 Gm. in spite of the fact that a good majority of the patients admitted an increased liking for, and consumption of, salty food.

A salt tolerance test was performed on all patients. It consisted of the administration of 10 Gm. of sodium chloride and 250 c.c. of water in addition to the identical food and liquid intake of the preceding control day. There was a rise of the twenty-four-hour salt excretion to 9.4 Gm. as an average, indicative of a retention of 73 per cent of the test salt for the whole group. Only 6 persons showed complete elimination of the added 10 Gm. of salt. On the other hand, complete retention of the test salt was noted in a similar number of cases, while the chloride excretion after salt intake was actually smaller than on the control day in 8 persons.

The twenty-four-hour urinary volume averaged 1,040 c.c. for the whole series; it decreased to 947 c.c. on the test day in spite of the fact that the liquid intake was 250 c.c. higher. In other words, the average retention was 343 c.c. It might be mentioned that water was retained in only one of the 6 patients who did not retain salt, whereas the other 5 eliminated increased amounts of urine. Thirty-two patients, i.e., a majority of the group, showed an actual decrease in urine output, and a slight increase, but less than the 250 c.c. of additional liquid intake, was noticeable in the remaining 13.

Estimation of blood chlorides carried out on whole blood was not found enlightening until the study was extended to the examination of chlorides separately in red blood cells and plasma.

The values for chlorides in the whole blood were found within the normal range from 480 to 510 mg. per cent. Higher values up to 530 mg. per cent were obtained only in 10 persons. The sodium chloride content of the red blood cells, however, ranged from 390 to 430 mg. per cent, exceeding the upper limit of our normal figures (380 mg. per cent) in 32 cases, that is, in 64 per cent of the series.

Studies of the sodium content of the blood were carried out only on the last 10 patients of this group. The values found varied between 230 and 264 mg. per cent, whereas control figures obtained with the same methods reveal the normal sodium level at 200 to 220 mg. per cent.

Determination of the basal metabolism showed that the average rate for the group was minus 10; the individual figures varied from minus 27 to plus 13, with the majority of the group well below minus 10. The specific dynamic action of proteins determined two hours after the intake of a small protein meal revealed an average increase of the metabolic rate of only 5 points. No rise at all was noted in almost one-half of the group; a considerable increase of the specific dynamic action of 23 to 28 points was observed in 6 persons. Upon elimination of these few patients who seem to deserve special consideration, the remaining 44 showed an average specific dynamic action as low as 2 points.

The fasting blood sugar ranged from 65 to 108 mg. per cent, with an average of 85 mg. per cent which is close to the lower limit of our normal range. Uric acid values were found to be from 2.2 to 4.8 mg. per cent, with an average of 3.4 mg. per cent which is definitely above normal. The differential count of the white blood cells showed variations of the lymphocyte count from 12 to 55 per cent, yet the average was 36 per cent, definitely connoting a relative lymphocytosis.

DISCUSSION

Our study seems to show the definite tendency in our group of patients to produce a low volume of urine with reduced sodium chloride output. There is marked retention of salt during the performance of the salt tolerance test, accompanied by water retention, which in some of the cases became visible in the form of swellings or seemed to precipitate a migraine spell. Clinically, two facts deserve emphasis: (1) the frequency of demonstrable vasomotor disturbances, such as white dermographism, together with a variety of related clinical manifestations, such as urticaria, Quinke's edema, rhinitis, and "sinus trouble"; (2) the prevalence of endocrine stigmatization. The latter includes,

first of all, the physical appearance of the patients who seem to fall mainly into two groups. One group included patients of both sexes who were tall, lean, and of slightly or definitely eunuchoidal proportions, while most of the patients of the other group showed peripelvic fat deposits such as are thought to be characteristic for pituitary insufficiency. The pattern or changes described as characteristic for a disturbed state of pituitary function (Goldzieher) conforms with the trend demonstrable in this group: low basal metabolism, decreased specific dynamic action of proteins, relative lymphocytosis, increased uric acid, and low normal fasting blood sugar.

That migraine is likely to occur in individuals, earmarked by their physical appearance as being affected with a disturbance of pituitary function, was stressed long ago by Timme, who suggested that the migraine attack might be precipitated by pressure of an enlarged pituitary upon the intracranial tissues. Such an enlargement might be the result of an increased blood and lymph flow to this gland, similar to the directly observable change in volume of the thyroid. Timme deserves credit for having pointed out the frequent coincidence of pituitary stigmatization and habitual headaches in association with angioneurotic manifestations, such as urticaria, hay fever, or asthma. Yet his explanation of increased intracranial pressure as the result of swelling and temporary enlargement of the pituitary is not tenable. X-ray studies show that the sella turcica was, in two of three cases, either enclosed by overlapping clinoid processes, or its aperture was narrowed to such an extent that bulging of the pituitary into the cranial cavity does not seem to be conceivable. An enlarged sella with an aperture wide enough to permit the pituitary to bulge into the cranial cavity was encountered only exceptionally in our series.

The relationship of the pituitary to intracranial pressure, and the causation of headaches, has aroused renewed interest through the findings of Riley, Brickner, and Kurzrok, who demonstrated the appearance of the pituitary gonadotropic hormone in the urine, generally from one to six days before the onset of a migraine spell. The hormone disappeared on the day of the attack, and occasionally appeared without being followed by headache. The excretion of the gonadotropic hormone was practically continuous in two patients with status migrainicus.

The findings of Riley and co-workers gained added significance through the studies of Kraus, who showed that increased intracranial pressure, regardless of its cause, stimulates the pituitary gland and causes hypertrophy of the anterior lobe. This hypertrophy is the anatomic expression of functional overactivity, demonstrated directly by the appearance of the gonadotropic hormone in the urine, and indirectly by the development of follicular cysts of the ovaries (Kraus).

The findings of Kraus permit the reinterpretation of the observations of Riley and associates in the sense that the increased excretion of gonadotropic hormone in migraine cases is the consequence of the increased intracranial pressure that precedes and eventually elicits the migraine attack. That increased intracranial pressure is capable of causing pain needs no argument. As a mat-

ter of fact, pressure or pull on the dura mater, and particularly the dural blood vessels, is considered to be the cause of most headaches (Pickering, Penfield, and Mc Naughton).

The mechanism of these functional headaches can be summarized as follows: Due to intracellular retention of salt, and especially of sodium, there is greater avidity of the tissues for water; the attack ensues if increased permeability of the capillaries, as a result of abnormal irritability of the vasomotors, permits a greater flow of moisture to the tissues. The retention of water and subsequent swelling of the tissues within the rigid cranium causes pain which lasts until the water is released through some process of adaptation in which the pituitary is again concerned in some way. The observation that termination of a migraine attack is often accompanied by polyuria is in accord with this view. As further corroboration, we should add that such headaches are quite common in women in connection with the menstrual period; they set in just preceding the menstruation, at a time when water retention is a physiologic event. These menstrual headaches are the best examples for the prevalence and combination of the two responsible factors: water retention and vasomotor instability. The former is proved by the premenstrual gain and postmenstrual loss in weight, while the increased capillary permeability of the premenstrual period is actually demonstrated by the "blister technique" on the skin of normally menstruating women (Peterson and Miller).

In contradistinction to the mechanism of these headaches, which seems to be clarified, the underlying pathology remains an open question. A constitutional, and often familial, element appears to be one of the factors which includes instability of the vegetative nervous system, particularly in respect to the vasomotors. Environmental factors, such as emotional upsets, nervous strain and fatigue, allergic phenomena, or endocrine disturbances are likely to aggravate the vasomotor neurosis. The influence of hormones upon the function of the capillary system is demonstrable experimentally, and clearly shown by clinical observation on menopausal women or castrates. Their outstanding complaints are referable to vasomotor disturbances, which respond well to estrogens, just as the flushes and allied symptoms occasionally noted in the middle-aged male, are relieved by administration of the male sex hormone.

Vasomotor disturbances alone do not cause headaches unless they are associated with a hydropexic state. The retention of water might be the result of long-continued, adverse nutritional habits, such as the excessive intake of salt, polydipsia, a diet low in proteins and high in carbohydrates with vitamin deficiency, as an added possibility. Barring extreme dietary indiscretions, however, it is unlikely that the normal human body, characterized by its power of adaptation, should be unable to take care of an overabundance of water or of food regardless of how unsuitable its composition. Hence, we must postulate a breakdown in the physiologic regulation of salt and water metabolism, such as that obtained in various endocrinopathies. The prevalence of endocrine stigmatization in patients suffering from headaches fulfills this postulate but does not answer the question as to the nature of the endocrinopathy involved, nor as to the hormonal factors that upset salt and water metabolism.

Deficiency of thyroid function may be one of the causes. It is well known that the myxedematous patient retains water and promptly responds to administration of thyroid extract with increased diuresis. Evidence of hypothyroidism, such as short stature, shortness of extremities, firm and dry integument, low basal metabolism, and elevated blood cholesterol, is obtained in quite a few, but certainly not in the majority, of the patients with endocrine headache.

The significance of the adrenal cortical hormone in respect to salt and water metabolism is shown both in the adrenalectomized animal and the patient with Addison's disease who are unable to retain sodium chloride and water normally. Correspondingly, administration of desoxycorticosterone in excessive quantities causes salt and water retention with increased blood pressure and visible edema. Clinically, however, there is no evidence of abnormal adrenal function in the headache patients, hence it would seem that the cortical hormone has no direct bearing upon our problem.

The opposite can be said in respect to the pituitary. Evidence of disordered function of the pituitary was our most common clinical finding, quite in accordance with Timme's observations. Pituitary hormonal factors of known metabolic activity include both those of the anterior and posterior lobes. The anti-diuretic hormone of the posterior lobe is supposed to act chiefly by interference with renal secretion. Important evidence, however, points also to effects directly upon the water content of the peripheral tissues. Experiments on frogs injected with posterior lobe extracts and submersed in water have shown that these animals gain weight by direct absorption and retention of water independently from the function of their kidneys (Brumm). Increased water content of the tissues following injection of posterior lobe extract was actually demonstrated by several investigators (Hines and co-workers, Heller and Smirk). It is significant, moreover, that the antidiuretic effect of the pituitary extract is soon followed by increased diuresis and elimination of chlorides. This justifies the assumption that tissue cells react to the posterior pituitary hormone, first with increased hydration, and subsequently after the effect of the hormone has worn off, with release of water and intracellularly stored sodium chloride.

Anterior lobe extracts have been shown to be diuretic (Teel); it was thought that this effect is referable to the thyrotropic hormone. It has been shown, however, that anterior lobe diuresis is independent of the thyrotropic factor (Mahoney and Sheehan) and is related to metabolic phenomena of a more complex nature (Richter). At any rate, the diuretic effects of the anterior lobe explain the apparent antagonism of the two lobes of the pituitary in respect to diabetes insipidus, for this syndrome develops with impairment of the posterior lobe, but only in the presence of functionally active anterior lobe tissue (v. Hann).

The activity of the anterior lobe enters consideration also in view of its gonadotropic secretion, which is the prerequisite of normal gonad function. The significance of estrogens for water metabolism has been pointed out in recent years by experiments in animals and women (Thorn and associates). The water retention produced by estrogens is in agreement with the fact that women retain water and gain weight at a time when the blood estrogen reaches its peak (At-

kinson and Ivy). Oliguria and refractoriness to diuretic procedures at this time are prevalent (Heilig). This is in striking contrast to the loss of weight and noticeable polyuria with increased elimination of sodium chloride (Thorn and associates) at the time of the postmenstrual low estrogen phase. Swelling of the face, extremities, or other parts of the body, common in the course of the premenstrual retention phase, is likely to subside promptly with the onset of the period (Sweeney).

Among the hydrating factors of hormonal nature, insulin must be mentioned, the injection of which causes water retention and may lead to visible edema. While there is no clinical evidence in our group of patients to inculcate the pancreatic islands and to assume an excess of insulin production, it would seem that the hydrating effects of insulin have considerable bearing upon the dietary management of the patient with headache. A diet rich in carbohydrates, especially in those directly convertible into glucose, is likely to stimulate insulin secretion and thus favor retention of water.

TREATMENT

Arguments "*ex juvantibus*" are usually dismissed as complacent and uncritical. If therapeutic procedures, however, are instituted for the correction of demonstrable metabolic abnormalities, and accomplishment of this task is associated with favorable clinical results, the therapeutic test stands up as additional evidence and should not be ignored. In the whole group of 50 patients, there was only one, a highly neurotic woman, who showed little improvement. It is significant that this patient was one of the few who showed no water retention and only a moderate (40 per cent) retention of the test salt. Forty patients, that is, 80 per cent, were completely and permanently relieved by treatment, while 9 showed considerable improvement both as to frequency and severity of their headaches.

This so successful treatment consisted of three elements: diet, medication, and endocrine therapy. The principles of the diet are largely the same as those outlined by Foldes; restriction of salt and liquid intake, high protein content with emphasis on purine-rich meats (liver, sweetbread, sardines), and considerable reduction in the consumption of carbohydrates. Fats are limited in the overweight, but are liberally given in the underweight patient.

The medication is based on two principles: mobilization and increased elimination of sodium, and correction of the imbalance of the vegetative nervous system. Ammonium chloride or potassium acetate given intermittently accomplishes the former and should be applied in the first two or three weeks of the treatment. Atropine combined with phenobarbital or preparations like belladonal are apt to accomplish the second part of our task. In patients with increased blood pressure, the use of bellergal seems to be preferable.

Endocrine medication consists of thyroid and pituitary extracts. It is fallacious to gauge the dosage of thyroid by the basal metabolic rate of the patient. The actual needs are best determined empirically, starting with 0.5 grain daily and gradually increasing the dosage to not more than 2, or at the utmost 3, grains daily. The patient's pulse rate is the best guide for thyroid

medication; slowing down of the pulse rate calls for increased, and undue acceleration for decreased, thyroid dosage. Injection of posterior pituitary extract is of great value, for increased diuresis and salt elimination follow after the initial antidiuretic effect has worn off. The injections should be properly spaced and given not more often than twice a week. The initial dose is 3 minims, with increments of one minim each time until mild abdominal cramps indicate that tolerance has been exceeded. These injections are given preferably in combination with a fresh and potent anterior lobe extract, especially in the presence of menstrual disturbances or other evidence of pituitary deficiency.

This treatment should be kept up for a period of about three months. Subsequently, both injections and medication are discontinued without the danger of recurrence, provided the spirit of the dietary management is kept alive. In other words, these patients must limit permanently the intake of salt and water and adhere to a high protein, low carbohydrate diet. Rigid dieting is not necessary, but overindulgence either in carbohydrates or in liquid consumption was responsible for relapses in several of our patients. Such recurrences promptly yielded to renewed enforcement of the original diet.

SUMMARY

A series of 50 cases of headaches, observed in endocrine patients, is presented, and evidence is submitted to show a general trend of sodium chloride and water retention. Stigmas pointing to an endocrine background were prevalent; they include: lower basal metabolism, decreased specific dynamic action of proteins, relative lymphocytosis, higher values for uric acid, sodium and chlorides in the blood, lower blood sugar, and abnormalities in the configuration of the sella turcica.

Endocrine headaches, including migraine headaches, are explained as the result of increased intracranial pressure. They develop when increased permeability of the capillaries permits increased flow of water to, and subsequent retention in, tissues which have stored abnormal quantities of sodium salts.

The retentional type of endocrine headache can be recognized by the decreased output of sodium chloride and water on performing the salt tolerance test.

The mechanism by means of which endocrine factors cause increased hydration of tissues is discussed.

The successful treatment of endocrine headaches consists of a high protein diet with restriction of salt, liquid, and carbohydrate intake, of medication with ammonium or potassium salts and belladonna preparations, and of endocrine substitution therapy with thyroid and pituitary extracts.

THE INFLUENCE OF TIME AND VOLUME FACTORS ON VENOUS PRESSURE RESPONSES TO PHYSIOLOGIC SALINE INJECTED INTRAVENOUSLY*

JOSEPH J. LALICH,† M.D., AND PAUL H. LORHAN, M.D., KANSAS CITY, KAN.

COHNHEIM and Lichtheim¹ demonstrated that a 0.06 per cent saline solution would elevate venous pressures without markedly affecting the arterial blood pressure. This finding was corroborated by subsequent investigators,²⁻⁶ who discovered that the systolic output and the size of the heart in diastole were dependent on the elevation of the venous pressure. Caughey⁸ suggested that venous pressure responses to intravenous saline be adopted as a test of cardiac function in human subjects, for which purpose he injected 1,500 c.c. of normal saline in thirty minutes. Gilligan and co-workers⁷ observed venous pressure responses to intravenous normal saline or to a 5 per cent glucose salt solution in hospital patients without heart disease. They concluded that, although venous pressure variations are dependent on the volume of fluid injected, the increment of venous pressure increase did not necessarily follow the degree of blood dilution.

Studies indicate that the time interval, and the volume of fluid injected are the factors which may modify venous pressure responses. Caughey controlled the time interval without correcting for the volume of fluid injected. Gilligan

†Bron research medical fellowship.

Received for publication, September 30, 1941.

studied blood dilution with variations in the time interval. No experiments are reported in which both the time and volume factors were controlled and studied. In this study either the time interval or the volume factor was constant, while the other variable was changed in order to determine the limits within which these factors influence venous pressure.

METHOD

Normal healthy adult dogs were anesthetized with intraperitoneal injections of 30 mg. per kilogram of sodium pentobarbital.* One and one-half inch No. 18 needles were used both for injection and measurement of venous pressure. Normal saline solution heated to body temperature was injected at a continuous rate into the vein of the foreleg by means of hydrostatic pressure from a graduated flask. Direct venous pressure measurements were made from the vein of the hindleg with a continuous drip saline manometer devised for the experiment. In a manometer of this type the respiratory movements may be observed continuously, while the constant flow of 15 to 20 drops of saline solution per minute prevented coagulation of the blood within the needle. At a rate of 15 drops per minute, 33 mm. of saline are necessary to overcome the resistance of the rubber tube and of the needle distal to the manometer. With the bottom of the manometer at the approximate center of the heart, the 33 mm. factor was subtracted from the observed readings in order to obtain actual venous pressure values. Respiratory fluctuations, and the velocity with which the added saline in the manometer dropped to the level at which pressures were in equilibrium, were the means used to check for obstruction within the measuring needle. The blood volume was calculated as one-eleventh of the body weight, and the normal saline injected is expressed as a percentage of this estimated volume. The change in venous pressure during the course of the experiment is expressed in millimeters of saline. In the shorter experiments venous pressure and volume inflow readings were observed every two or three minutes, whereas in the longer experiments these observations were usually checked every five minutes. A total of 83 experiments on 25 dogs were carried out. Ten control experiments in which venous pressures were measured for fifteen-minute intervals showed the normal variations under surgical anesthesia to be less than ± 10 mm. of saline. Fifty experiments were performed with the time interval fixed at fifteen minutes, while the inflow was changed. Another 23 experiments were carried out with the fluid inflow fixed at approximately 50 per cent of the calculated blood volume, while the time was varied.

RESULTS

The results have been expressed in graphic form for sake of brevity, and to illustrate the variability of response in normal dogs under surgical anesthesia. Each point in Graphs 1 and 2 represents the total fluid inflow, and the change of venous pressure in millimeters of saline during the course of one experiment. The broken lines representing the most probable response have been drawn so as to divide the points equally.

*Donated through the courtesy of the Abbott Laboratories.

Graph 1 illustrates that, with the time interval fixed at fifteen minutes, greater volumes of normal saline produce greater increments in venous pressure. Volumes greater than 10 per cent of the blood volume have to be injected in this time interval before any increase in venous pressure may be expected. Injections equal to 75 per cent of the blood volume in fifteen minutes produced the maximal response of venous pressure rise to 89 mm. of saline.

Graph 1.—Fluid injected expressed in percentage of estimated blood volume.

Graph 2.—Saline injected equals 50 per cent estimated blood volume. The volume is constant and the time interval is altered.

Graph 2 shows that with the amount of normal saline injected maintained at approximately 50 per cent of the blood volume; as the time interval of injection is prolonged, the increase in venous pressure becomes progressively less, so that beyond forty-five minutes an animal may show no increase in venous pressure.

Graph 3 shows five individual experiments (numbering from top to bottom) representative of the whole group.

The majority of the responses were either gradual increases or ones that showed abrupt breaks as do curves 4 and 5. Straight lines usually occur when the volume of fluid injected is less than 35 per cent of the calculated blood volume. Changes in the slope of the line develop when the volume injected is 40 per cent or more of the calculated blood volume. Increases in venous pressure appear to be directly proportioned to the volume of saline solution injected. Curves like 2 follow either alterations in velocity of fluid injection or an increase in resistance to the flow of saline from the manometer, due to the poor position of the needle within the vein.

Graph 3.—Individual responses.

DISCUSSION

The relationship between volume of fluid injected and the elevation in venous pressure appears more evident if the time interval is less than fifteen minutes. When the time interval is forty-five minutes or more, diffusion and vasodilatation can compensate fully, so that injections of normal saline equal to 50 per cent of the calculated blood volume may show no elevation in venous pressure. Injections of physiological saline at constant velocities will produce venous pressure increases closely approximating a straight line; shifting the velocity inflow in either direction will cause a corresponding change in the slope of the venous pressure curve. Even though different animals vary as much as 50 mm. of saline for the same volume of fluid injected, on repeated trials in any one dog the results agree closely. None of the animals developed cardiac decompensation following these injections or showed any deleterious effects on the following day.

Moderate pressure, produced by placing one's hand on the animal's chest, caused an increase of venous pressure from 4 to 15 mm. of saline. During the experiment the heart rate usually accelerated and the apex impulse became more forceful. If the animals shivered or stretched their extremities, venous pressures would increase from 10 to 30 mm. of saline. Respiratory movements showed that inspiration produced depression in the venous pressure measuring 2 to 5 mm. of saline, which returned to the original level during expiration. The majority of initial venous pressure readings of saline were between 50 and 70 mm., the lowest value was 29 mm., and the highest was 105 mm.

CONCLUSIONS

1. Both the volume of normal saline injected and the time interval are capable of altering the response of venous pressure to intravenous fluids.
2. With a fixed time interval of fifteen minutes, volumes less than 10 per cent of the calculated blood volume may cause no change in venous pressure.
3. Volumes of saline equal to 50 per cent of the calculated blood volume will show a slight or no increase in venous pressure if the time interval exceeds forty-five minutes.
4. Intravenous saline solution equal to 75 per cent of the calculated blood volume injected in fifteen minutes is tolerated without harmful effects.

CARDIOSPASM*

OBSERVATIONS ON THE USE OF PROSTIGMINE: A CLINICAL AND EXPERIMENTAL REPORT

JACOB MEYER, M.D., AND H. NECHELES, M.D., PH.D.
CHICAGO, ILL.

CLINICAL and experimental observations on the use of prostigmine as an aid in the treatment of cardiospasm and mega-esophagus are reported. The accepted therapy for cardiospasm in the past has been (a) gastric lavage; (b) dilatation of the cardia; (c) the use of antispasmodics. Psychotherapy, diathermy,¹ and vitamin B₁² have been reported to be of value. These measures have been effective to a degree in relieving the patient of discomfort and in improving his general nutrition. The esophagus has in most instances remained the same size, and patients have had recurrent symptoms but with a minimum of discomfort despite the large esophagus. Much evidence has accumulated recently to show that in a number of instances cardiospasm is related to damage to vagus fibers or to damage and loss of ganglion cells of the myenteric plexus of the esophagus at the cardia.³

The theory of Hurst and associates⁴ proposed that following destruction of the parasympathetic myenteric plexus, the sympathetic nerves act unopposed and keep the cardia closed, so that the normal opening reflex of the cardia cannot take place at swallowing^{5, 6} and dysphagia occurs, with gradual dilatation of the esophagus. This theory is supported indirectly by observations of Klee⁷ on the cat: after section of the splanchnic nerves the cardia lost its power to open reflexly. This is comparable to the tonic "locking" of certain muscles in mollusks after sectioning of their motor nerve. The term "achalasia" is certainly better than "cardiospasm," although it may not cover the entire field of clinical experiences. It is difficult to conceive, *i. e.* that degenerative changes in the myenteric plexus of the esophagus occur in cases of functional obstruction of the cardia in hysteria; or in reflex disturbances from the abdominal viscera which sometimes improve after operation (cholecystitis, appendicitis, etc.). Recently, intractable cardiospasm has been relieved successfully by bilateral cervicothoracic sympathetic ganglionectomy.⁸ This may be considered as proof of sympathetic achalasia, although a longer period of time is necessary for judging the permanency of the beneficial effects of the operation.

From the foregoing, drug therapy for achalasia and mega-esophagus can be elaborated on a logical basis, assuming that we are dealing with a true

*From the Departments of Medicine and of Gastro-Intestinal Research, Michael Reese Hospital, Chicago.

Received for publication, October 3, 1940.

achalasia, that is, a condition in which degenerative changes have taken place in the myenteric plexus of the lower esophagus, through which the parasympathetic nerves effect normal peristalsis. Drugs that affect the parasympathetic system may be used to produce increased tonus and peristalsis of the esophagus, and thus push the food into the stomach. At first, we assumed that some parts of the plexus, upon which these drugs would act, were still functioning. Later we found that certain parasympatheticotropic drugs act not only on parasympathetic endings, but also on the smooth musculature directly (v.i.). Eserine and prostigmine were employed, the latter being the drug of choice because it lacks the disagreeable by-effects of the former.

We first made observations on two patients with very pronounced dilatation of the esophagus of eleven and twelve years' duration. The histories are briefly summarized below. At the beginning of the study we made certain that there was no organic stricture or stenosis of the esophagus. This is a precaution which we feel is necessary to emphasize.

M. F., female, aged 21 years, was admitted to the Michael Reese Hospital on May 8, 1938, because of right lower lobe pneumonia. During convalescence the patient reported that she had a "stricture" of the esophagus and difficulty in swallowing food. The history revealed that the symptom began rather suddenly at the age of 12 and was associated with a severe emotional conflict with her parents. At this time she was admitted to the Sarah Morris Hospital and treated for esophageal "stricture" by dilatation. After a short stay in the hospital her condition improved and she was discharged. In 1929 she was readmitted to Michael Reese Hospital because of a cough and loss of weight. A dilated esophagus was noted. Fluoroscopy and roentgen examination (July 21, 1929) showed mega-esophagus and cardiospasm. Following repeated dilatation of the cardia her condition again improved. Studies during the patient's convalescence on her last admission to the hospital on May 19, 1938, revealed a marked dilatation of the intrathoracic and apparently diaphragmatic portion of the esophagus, with a constriction just above the stomach. On May 27, 1938, an attempt to pass a dilator bougie through the cardio-esophageal hiatus was unsuccessful. The patient was given physostigmine per os 1/150 grain daily, with daily gastric lavage followed by dilatation with a Mosher dilator for one week. This made her feel better and she had less difficulty in getting the food to "go down." She was discharged from the hospital on June 16, 1938, and observation was continued in the clinic. At this time the following routine procedure was pursued: Dilatation was discontinued. Prostigmine* was given by mouth, 15 mg. three times daily, and the patient was advised to return to the clinic in four weeks. At the end of this period she was reported to be improved. Swallowing of solids was better, and she did not need to drink fluids to force food down. Nevertheless, the patient requested dilatation since she felt that this procedure, in addition to the prostigmine, had helped her. Dilatations by the Mosher dilator, at approximately two-week intervals, and then at monthly intervals, were continued. Roentgenograms and fluoroscopic observations of the esophagus were made over the period, and it appeared that the esophagus was smaller.

We have observed this patient for over two years. During periods, when prostigmine was withheld, the patient would return with more complaints and ask that the drug be continued. This was true even though she had had periodic dilatation of the cardia. The patient had been dilated previously at other institutions, but she had not experienced the same degree of improvement as from prostigmine and dilatation. She had also undergone an extensive course

*Supplied by Hoffmann-LaRoche Co.

of psychotherapeutic treatment at another institution with no apparent improvement. The patient admits that her symptoms are aggravated during severe emotional strain.

As a final check, we made fluoroscopic observations of the effect of the injection of prostigmine on the esophagus of this patient. Under fluoroscopic observation a barium meal was administered and 1 mg. of prostigmine was injected intramuscularly. Fifteen minutes later increased peristalsis and tonus (which reached its peak in twenty minutes) were observed. The increased contractions of the esophagus were particularly marked above the cardia, and the barium meal was emptied rapidly into the stomach. Intramuscular injections of 0.5 mg. of adrenaline hydrochloride had no visible effect on the esophagus.

R. N., female, aged 40 years, was admitted to the Michael Reese Hospital on August 6, 1937, after five days of repeated emesis. The past history revealed that she had a cholecystectomy in 1928, and subsequent to this had developed a large esophagus for which she had repeated dilatation with moderate relief. In 1933 the patient had a thyroidectomy. She was an emotional person, with quite a complicated social background. X-ray revealed an unusually large esophagus. The patient was placed on prostigmine, per os, 15 mg. three times daily, and later twice daily, and has been receiving same intermittently for approximately two years. At first she seemed to be distinctly improved, but as she became adjusted to the huge dilatation, it was most difficult to determine what symptomatic improvement we were obtaining. Both dilatation by Mosher dilator and prostigmine seemed to improve her condition, and like the other patient, she expressed the opinion that the prostigmine made her feel better. On the other hand, she had so many emotional conflicts that it was hard to evaluate the improvement.

The effect of prostigmine (and other drugs) on the esophagus was tested under fluoroscopic observation. At 9 A.M. 1/150 grain of atropine sulfate was injected intramuscularly. The patient's blood pressure was systolic 110 and diastolic 84 at 10 A.M. At 10:15 A.M. barium milk mixture was given, but the patient managed with difficulty to drink about $\frac{3}{4}$ cup. The esophagus was seen fairly filled, with shallow peristaltic waves traveling downward. At 10:30 A.M. 1 c.c. of 1:2,000 ergotamine tartrate was administered intramuscularly. One minute later much deeper and much more frequent waves were observed moving down the esophagus than before. At 10:50 A.M. the blood pressure was systolic 100 and diastolic 70. More barium mixture was given, and shallow peristaltic waves were observed. One-half milligram of prostigmine was injected intramuscularly. The depth of the peristaltic waves increased within a few minutes, at times giving the impression of contraction rings traveling down the esophagus, and a greater frequency of peristalsis and increase of tone of the organ was observed. At 11 A.M. the blood pressure was systolic 118 and diastolic 85. One milligram of adrenalin hydrochloride was injected intramuscularly. Peristalsis, which after the injection of prostigmine had been present continuously, seemed to be somewhat increased. No untoward effect of the drugs given above was noted. At 11:10 A.M. the blood pressure was systolic 114 and diastolic 75.

We realize the difficulties in evaluating therapeutic results, particularly in this condition. It is well recognized that mere dilatation by any type of dilator will improve the well-being of a patient with achalasia, and will diminish the quantity of esophageal retention. It was our thought, that prostigmine, by acting on the parasympathetic plexus, would increase peristalsis and tone of the esophagus. Our observations definitely show that it does increase peristalsis, particularly in the lower portion of the esophagus. In that sense a propelling action of prostigmine is accomplished. Our patients stated that they were better with prostigmine and dilatation. It must be recognized that the achalasia and esophageal dilatation in our two patients were of long duration and of extreme

character. We suggest the use of eserine or prostigmine in early cases. Likewise, it is suggested that hypodermic medication rather than oral administration be tried in cases of chronic dilatation.

ANIMAL EXPERIMENTS

In order to check the effects of prostigmine on the esophagus, experiments were performed on dogs. The animals were anesthetized with nembutal, and three balloons were inserted into the esophagus at different levels: just above the cardia, into the midportion, and just below the glottis. The balloons were connected to water manometers and were inflated with about 5 cm. of water pressure. Blood pressure was recorded in the usual way with a mercury manometer connected to the carotid artery. In Experiment 1 (Fig. 1) respiration was not interfered with, and the curve showed its rhythmic effects on

Fig. 1.

esophageal motility. One milligram of prostigmine injected intramuscularly produced a considerable increase of tone and peristalsis in the lower portion of the esophagus, lasting for about twenty minutes, while the upper portion of the esophagus was little affected. The animal in Experiment 2 (Fig. 2) was given artificial respiration, its chest was opened widely, and both phrenic nerves were cut in order to eliminate the effects of respiration on the esophagus. Injection of 1 mg. of prostigmine intravenously produced considerable rise of tone and peristaltic activity in the lowest portion of the organ, much less in the middle and very little in the upper portion. The effects lasted approximately fifteen minutes. In Experiment 3 (Fig. 3) the same operative procedure was followed

as in Experiment 2. Three-tenths milligram of prostigmine intravenously was followed by a rise of tone and motility of the lowest portion of the esophagus, lasting for about twenty-five minutes. The middle portion showed little, and the upper portion showed no effects of the drug. One hour later 1 gamma of acetylcholine hydrochloride was administered intravenously; it had little or no effect on the esophagus while a distinct transient drop of blood pressure occurred. Following this, 4 mg. of atropine sulfate were injected intramuscularly. Twenty minutes later 1 gamma of acetylcholine was injected again, and the negative response of blood pressure indicated that atropine had taken effect.

Fig. 2.

Following this, 0.3 mg. of prostigmine was injected intravenously; this dosage was repeated twenty minutes later. Each time a marked rise of tone and contractions of the lowest portion of the esophagus occurred, but the middle and upper portions did not respond. Fifteen minutes after the second injection of prostigmine, 1 gamma of acetylcholine was given intravenously, with no effect on blood pressure. This showed that the antagonistic effect of the atropine still prevailed.

These experiments demonstrated two facts to us: First, that prostigmine raises tonus and rate of peristalsis of the esophagus and acts mainly on its lower third. Second, that prostigmine acts on this organ not only through stimulation of its parasympathetic innervation, but also through a direct effect on its

musculature. We draw this latter conclusion from the fact that prostigmine still affected the organ after the parasympathetics were paralyzed by atropine, as proved by the ineffectiveness of acetylcholine administered repeatedly after atropine. It seems, therefore, that prostigmine is a useful drug in true achalasia in which more or less of the extrinsic and intrinsic parasympathetic innervation of the lower esophagus has been destroyed by pathologic processes. The observations on the dog agree with those obtained on the two patients reported in this paper. The effect of ergotamine on the second patient is of interest, because this drug is known to decrease and, in a sufficient dose, to abolish and reverse the typical effects of sympathetic stimulation. Since in achalasia there is a predominance of sympathetic innervation of the lower esophagus and cardia, it would seem logical to treat such patients with a combination of eserine or prostigmine and ergotamine. This is under experimental investigation at present.

Fig. 3.

SUMMARY

Two patients suffering from achalasia and dilatation of the esophagus were treated by oral administration of prostigmine. Both of them seemed to be benefited by this therapy. Fluoroscopic observations revealed that tonus and peristaltic rate of the esophagus were markedly increased following intramuscular injection of prostigmine. Injection of ergotamine into one patient likewise revealed increased tone and peristaltic rate of the esophagus. Since achalasia of the cardia has been assumed to be due to diminished or absent function of parasympathetic innervation and prevailing sympathetic innervation, prostigmine and ergotamine seem to offer a logical and promising method of treatment of this condition.

Experiments on anesthetized dogs confirmed the observations made on the patients and further reveal that prostigmine acts not only through stimulation of the parasympathetic innervation of the esophagus, but also through a direct effect on its musculature.

CHRONIC, ATROPHIC TYPE OF BRUCELLOSAL ARTHRITIS

E. GOLDFAIN, M.D., OKLAHOMA CITY, OKLA.

IT IS well established that different types of systemic infection may cause polyarthritis which, in its clinical appearance and symptomatology, is essentially indistinguishable from true atrophic arthritis. That is essentially true when such arthritis appears in women, in whom atrophic arthritis is most common.

Chronic brucellosis is in course of evolution. At least in the Southwest physicians are becoming increasingly "brucellosis conscious," and rightly so. In keeping with this general trend, and as chronic arthritis has a varied etiology, it is now part of good diagnostic routine to do agglutination and opsonocytophagocytic tests as well as a skin test of each patient for the presence of brucellosis. Reports as to the number of cases of chronic arthritis or chronic fibrositis having positive serologic and skin tests for brucellosis are the subject of a paper in process of preparation. Herein I set forth a syndrome occasionally found in which the pathology is from a clinical standpoint that of atrophic arthritis. Yet, the etiology is that of chronic brucellosis. The two cases presented are representative instances. They occurred in females. Both had typical fusiform spindle-shaped swellings of the interphalangeal joints of the fingers of both hands, as well as involvement of joint tissues in other parts of the body. Joint involvement, from the beginning, was essentially persistent and was not subject to regression. Its development was insidious and progressive. Presence of cold, clammy skin of both hands was noted. Past removal of apparent foci of infection had in general caused no regression of the arthritis. Physical therapy and other measures failed to relieve or to interrupt the disease course. A familial history of arthritis was absent. In one case knee and shoulder joints were definitely involved by a type of fibrous tissue swelling that is often seen in atrophic arthritis. An outstanding x-ray finding was that the bones of the involved joints did not reveal the narrowing of joint space and the decreased density of the ends of the bones forming the joints, which is seen

in cases of typical atrophic arthritis after the process has been present for some period of time, as was the case in these individuals. Laboratory tests revealed a lack of marked degree of secondary anemia that is often present in atrophic arthritis. Streptococcal antibodies were absent. Gastric analysis was normal. The gonococcal complement fixation test was negative. An active red blood cell sedimentation test was present. The Schilling differential count showed a mild increased shift to the left. An important clinical laboratory finding was a positive agglutination test for undulant fever.

The opsonocytophagic test also revealed a strongly positive test, being in one case as high as 100 per cent mild, moderate, and marked phagocytosis. In both cases skin test was strongly positive at the end of forty-eight hours and for a few days thereafter.

Fig. 1.—A, Case 1. M. R. B. X-ray of hands. Chronic arthritis, atrophic type, four years' duration. Note lack of joint space narrowing and demineralization. B, Same case as shown in Fig. 1. X-ray of right elbow. Note lack of bony pathology.

CASE 1.—Mrs. M. R. B. was first seen in the summer of 1935, when typical spindle-shaped fusiform swellings involving the interphalangeal joints of nearly all her fingers were present. Her physician husband was informed that it appeared to be a case of atrophic arthritis. She was carefully investigated in due time for focal infection, but none was found to be present. Streptococcal antibodies were not present. Agglutination tests for undulant fever were strongly positive. The opsonic index test was positive. The skin test was strongly positive.

X-ray examination of the involved joints of the fingers simply revealed the normal bones that form the involved joints. Diffuse soft tissue swelling could be seen by x-ray shadow. X-ray examination made of her hands in January, 1939, four years after the onset of her trouble, revealed normal joint spaces and bones forming the involved joints, except for very slight lipping in the terminal joints of both fifth fingers. Narrowing of joint space and demineralization, such as one sees in atrophic arthritis, particularly atrophic arthritis present over such a long period of time, were absent.

X-ray examination of the right elbow joint was made in September, 1937, because of joint symptoms, but it failed to reveal any bony pathology.

The patient's past history was essentially negative, except for influenza and a miscarriage in 1927. An appendectomy and curettage were done in 1927, as was the removal of one cystic ovary. In the latter part of 1927 chills at intervals appeared, accompanied by wringing sweat and a feeling of stiffness all over her body, the stiffness involving most

markedly both upper extremities, so that for a period of time they could be used only very little; other joints of her body were involved. A tonsillectomy was performed in 1927. Very slowly and gradually she became better of her rheumatism, but a marked nervous condition developed. Treatment for her nervous condition resulted in gradual clearance of her rheumatism. Prior to the onset of the typical symptoms of arthritis in her hands, she felt ill for a long period of time and lost weight. The patient is of the age during which hypertrophic arthritis develops.

As a result of brucella bacterin therapy administered by her physician husband over a period of a year she improved in every way, clinically and from the standpoint of x-ray examination and laboratory findings.

The absence of findings, laboratory, x-ray, or clinical, that would explain her atrophic arthritis, plus positive skin, agglutination, and opsonic index tests for brucellosis, as well as her admirable response to treatment for chronic brucellosis, with no definite relapse after treatment had been completed, justifies labeling this case as one of brucelloidal arthritis, chronic, atrophic type. The case illustrates the chronicity of illness that may be present in individuals plus the essential relapses and improvements that occur. This may happen in atrophic arthritis.

Fig. 2.—Case 2. Mrs. R. S. X-ray of hands. Chronic arthritis, atrophic type. Note lack of demineralization and articular cartilagenous involvement.

CASE 2.—Mrs. R. S. was first seen in January 14, 1937. Her history dated back two years, beginning with pain and discomfort in the left shoulder joint. These symptoms appeared in spells at irregular intervals over a period of some few months. Moderate response at first to salicylates occurred. Thereafter the arthritis appeared insidiously, and became worse progressively. Many joints became involved, especially the hands, knees, and feet, as well as the shoulders and elbows. She had some teeth extracted and her tonsils removed. She had taken treatment at bathing resorts. Scarlet fever and whooping cough occurred in childhood. She has had two pregnancies, one of which was aborted with no ill effects. The abortion took place after the onset of her arthritis. The family history is negative.

Physical examination was negative, save for the presence of marked motion limitation of both shoulder joints and right elbow. Cold, clammy perspiration was present in both hands. Wrist and interphalangeal finger joints were indurated. The involved finger joints revealed typical spindle-shaped fusiform swellings seen in atrophic arthritis. Knuckle joints were also enlarged. A low-grade inflammatory infiltration of the fibrous tissues of both knees, with moderate restriction of flexion, was present. Lateral pressure over the phalangeal joints caused pain. Adherent tubes were questionably present on pelvic examination.

X-ray examination revealed a lack of joint space narrowing and an absence of demineralization of the bones forming the joints. A faint shadow of the soft tissue swelling was noted.

Laboratory findings revealed absent streptococcal antibodies and negative gonococcal complement fixation test. Gastric analysis, blood count, urinalysis, and stool examination were negative. The red blood cell sedimentation test showed a moderately active curve. Agglutination test for undulant fever showed strongly positive results in dilutions of 1:50. Opsonic index test for undulant fever revealed mild, moderate, and marked degree of opsonocytophagocytosis to 100 per cent. The skin test for undulant fever was strongly positive 4+ at the end of forty-eight and ninety-six hours.

The patient responded well to brucellosis treatment and at the end of two years is practically cured.

Diagnosis: Brucellosal arthritis, chronic, atrophic type.

Fig. 3.

SUMMARY

1. The two patients presented had clinical objective and subjective findings that would stamp them as cases of atrophic arthritis.

2. X-ray findings, even though the condition had been present in each case for a long period of time when first seen, and for at least two years thereafter in one case and four years thereafter in the second, continued to reveal none of the findings characteristically seen in true atrophic arthritis.

3. From a laboratory standpoint findings that are usually noted in atrophic arthritis were absent, save for the presence of a quite active sedimentation test in each instance. Both cases revealed strongly positive agglutination, opsonocytophagic, and skin tests for brucellosis.

4. Each patient has responded quite satisfactorily to management for chronic brucellosis: one case, Mrs. R. S., as soon as she improved on treatment for chronic brucellosis, discontinued treatment. The condition, however, reappeared, and continuation of proper treatment has resulted in practical cure.

CONCLUSIONS

1. Two cases are here presented which are typically atrophic arthritis from a clinical standpoint.

2. Laboratory findings are presented which indicate that the arthritis was due to chronic brucellosis.

3. X-ray findings are set forth indicating that chronic brucellosis does not cause articular cartilage destruction nor epiphyseal bone involvement such as is in due time present in practically all cases of atrophic arthritis.

MULTIPLE INVASION OF THE BLOOD STREAM*

ABRAM KANOF, M.D., AND BENJAMIN KRAMER, M.D., BROOKLYN, N. Y.

IT IS well known that bacteriologic study of infected tissue may disclose more than one organism. Kolle and Hebsch,¹ and Ford,² described many such cases and developed an elaborate classification. However, there has been no systematic study of multiple invasion of the blood stream. A few references have been made to cases of septicemia complicated by a secondary bacteriemia, but we have seen no report devoted to the subject of multiple blood stream infection.

In 1906 Libman³ reported 98 cases of sepsis, among which were several instances of multiple infection. The combinations were: streptococcus + gonococcus, streptococcus + *B. proteus*, *B. coli* + streptococcus + *Micrococcus albus*, *Staphylococcus aureus* + *pyocyaneus*, and three cases with staphylococcus + streptococcus. Scott⁴ reported a series of 80 patients with urologic disorders who had had routine blood cultures taken with each chill. They found five (6 per cent) who had more than one organism in the blood at the same time. The combinations were staphylococcus or streptococcus with either *B. proteus* or *B. pyocyaneus*. Neuhoﬀ, Amfses, and Hirshfeld⁵ reported a series of 150 patients with sepsis. In only one patient was there a multiple infection, a patient with both streptococci and staphylococci in the blood. Adams⁶ reported a series of 12 patients with sepsis, two of whom had multiple blood invasion; in one patient an embalming wound resulted in a fatal septicemia with *Streptococcus hemolyticus* and *Vibrio septique*; and in another patient, incision of an area of cellulitis was followed by a fatal sepsis with staphylococcus and *Streptococcus hemolyticus*. Similar series were reported by Shanks and Khan,⁷ Warren and Herrick,⁸ Cadham,⁹ Trask,¹⁰ and by Doane and Cates.¹¹

The following is a summary of the combinations described by the aforementioned authors:

Streptococcus + gonococcus	-	1
Streptococcus + <i>B. proteus</i>	-	1
Streptococcus + <i>B. coli</i> + <i>Micrococcus albus</i>	-	1
Staphylococcus + <i>B. pyocyaneus</i>	-	2
Streptococcus + staphylococcus	-	11
Streptococcus + <i>Vibrio septique</i>	-	1
<i>B. typhosus</i> + enterococci	-	5
Streptococcus + <i>B. typhosus</i>	-	1
Streptococci + <i>B. coli</i>	-	1
<i>B. proteus</i> + <i>B. coli</i>	-	1
Staphylococcus + <i>B. coli</i>	-	1
Staphylococcus + <i>B. influenzae</i>	-	1
Pneumococcus + influenzae	-	2
Staphylococcus + pneumococcus	-	2
Staphylococcus + pneumococcus + <i>B. coli</i>	-	1

*From the Department of Pediatrics, Jewish Hospital of Brooklyn.
Received for publication, October 8, 1940.

On the other hand, many authors present large series of septic patients where there is no mention made of multiple infections. These include Bean,¹² who reports 109 patients; Crocker, Valentine, and Brody,¹³ who report 52 patients; Dennett¹⁴ and Thelander,¹⁵ who report, respectively, 115 and 32 cases in children; Glass,¹⁶ 63 cases; and Kolmer,¹⁷ 282 cases. This makes a total of 652 patients with sepsis in whom no instance of multiple infection is mentioned.

In this paper we are presenting 24 children who showed more than one organism in the blood stream during their period of hospitalization. These cases were collected over a five-year period and represent 8 per cent of all patients with bacteremia studied during this time.

We found it best to classify these patients as follows:

- (1) True mixed septicemia.
- (2) Septicemia complicated by a secondary bacteremia.
- (3) Spurious mixed septicemia.
 - a. Where the second organism is a variant of the first.
 - b. Where a casual invader appears in the course of a sepsis.

METHOD

All patients with fever admitted to the pediatric wards between the years 1931 and 1935 had blood culture studies. The blood cultures were taken according to standard methods by an intern assigned to the service. All work was supervised by one individual, giving the results a good degree of uniformity throughout the years during which these cultures were taken. Fourteen cubic centimeters of the patient's blood were drawn and poured into culture media at the bedside. Five cubic centimeters were injected into each of two 200 c.c. Erlenmeyer flasks. The first flask contained 125 c.c. of veal infusion broth at pH 7.2; the second flask contained 125 c.c. of 2 per cent dextrose veal infusion broth of the same hydrogen-ion concentration. The remaining 4 c.c. were divided equally to form two pour plates, one with a 2 per cent dextrose veal infusion agar, and the other with a tube of plain veal infusion agar. Daily transplants were made from the two flasks, and smears were stained at the same time.

The invasion was considered "large" if there were more than ten colonies per cubic centimeter of blood. It was called "small" if only the liquid media showed growth. The size of invasion was "medium" if the broths were positive, but there were less than ten colonies on the plates.

I. TRUE MIXED SEPTICEMIA

By the term "true mixed septicemia" we refer to a type of sepsis where more than one organism is found in the same blood culture. There were nine patients in this group. The combinations of organisms were as follows:

1. <i>Streptococcus hemolyticus</i> + <i>B. coli</i>	4 cases
2. <i>Streptococcus hemolyticus</i> + <i>B. coli</i> + <i>Staphylococcus aureus</i>	1 case
3. <i>Streptococcus hemolyticus</i> + <i>Staphylococcus aureus</i>	2 cases
4. <i>Streptococcus hemolyticus</i> + <i>Pneumococcus</i> type XXI	1 case
5. <i>Staphylococcus aureus</i> + <i>B. coli</i>	1 case

The number of colonies isolated of each organism was recorded as "numerous" in five instances; "large" and "medium" in two; "small" in one, and "unknown" in one.

In six patients of this group the blood cultures were performed post mortem. These patients lived for such a short time, or were so desperately sick that a culture was not taken during life. In each instance a cardiac puncture was performed immediately after suspension of respiration, and the blood was poured into media at the bedside.

The significance of the blood cultures in these cases depends on what significance can be placed on post-mortem cultures. If the blood after death is rapidly invaded with many organisms which have no relation to the disease process, then these cases are of no practical significance. In our experience, however, such rapid nonspecific growth does not ordinarily occur. Of 1,309 patients from whom we cultured specimens over a period of five years, 171 had the blood drawn immediately after death. Of these, fully 50 per cent were sterile. We agree with White¹⁸ in supposing that these post-mortem cultures reveal the etiologic agents of disease which cannot grow out during life, but multiply rapidly after death because the immunologic resistance of the body is no longer intact.

Most patients in this group were very young. Three patients were less than a month old, four were less than 6 months old, one was 3 years, and one was 6 years old. There were four girls and five boys. Short case histories of these nine patients are given, but certain facts in the clinical course are particularly striking. Six patients were admitted to the hospital in a markedly toxic state and died within twenty-four hours. The other three died within four days after admission. The majority suffered from debilitating illnesses before admission. Six had been sick for one month or more, and three had been ill for a period of two weeks. In two patients the septicemia followed an operation. One patient had had a herniotomy; the other had an abscessed kidney removed. The most constant symptom was diarrhea, which occurred in six of the nine patients. The case histories follow:

CASE 1.—H. K., a 2-month-old male, was operated upon for an inguinal hernia because of mild obstructive symptoms for four days. He left the hospital on the tenth day following operation but returned two days later with marked diarrhea and dehydration. He died soon after readmission. Cardiac puncture immediately after death revealed 34 colonies per cubic centimeter of blood of *Streptococcus hemolyticus*, and 35 colonies of *B. coli*. Autopsy revealed partial atelectasis and empyema, lipoid pneumonia, parenchymatous degeneration of the liver, kidneys, and adrenals, and a well-healed operative scar.

CASE 2.—M. S., a 3½-year-old girl, was admitted with acute lymphatic leucemia. One week after admission her blood culture was sterile, but ten days later she developed acute parotitis and died. Cardiac puncture immediately after death revealed innumerable colonies of both *Streptococcus hemolyticus* and *B. coli*. Autopsy report confirmed the clinical diagnosis.

CASE 3.—G. T., a 6-month-old girl, was admitted with acute rhinopharyngitis, diarrhea, marked dehydration, and rickets. She seemed to improve for a few days with treatment, but at the end of the second week she developed cellulitis of the back and lapsed into acidosis and dehydration again. This time she did not rally and nine days later she died. Terminally, she developed the signs of a diffuse bronchopneumonia. Cardiac puncture immediately after death showed numerous colonies of *Streptococcus hemolyticus* and pneumococcus type XXI.

CASE 4.—I. B., a 3-week-old male infant, was admitted after having been ill for two days with acute rhinopharyngitis, marked cervical adenitis, and cellulitis of the neck. Four days later there was fluctuation in the area of cellulitis, and it was incised and drained. The child developed a marked diarrhea which persisted for three weeks. He then developed a diffuse bronchopneumonia and died. Blood culture on admission was sterile, but a cardiac puncture immediately post mortem showed numerous colonies of *Staphylococcus aureus* and *Streptococcus hemolyticus*.

CASE 5.—B. S., a premature female infant, was admitted from the nursery on the fifteenth day after birth, with an acute upper respiratory infection and diarrhea. Despite treatment the child grew steadily worse, developed signs of thrombosis in the cranial sinuses, and died. On admission the blood culture was sterile but cardiac culture immediately after death showed *Streptococcus hemolyticus* and *B. coli*. Autopsy revealed fetal atelectasis, passive congestion of the viscera, gastro-enteritis, focal pneumonia, focal necrosis of spleen and suprarenals, and thrombi in the cranial sinuses.

CASE 6.—L. R., a 3-month-old male, was admitted with diarrhea and marked dehydration, after having been sick with an acute upper respiratory infection for two weeks. With treatment the dehydration seemed to improve, but the patient developed a cellulitis of the left hand, and a day later, gangrene of the right hand. Blood culture showed *Streptococcus hemolyticus* and *B. coli*. The patient died three days later. Autopsy showed cellulitis of the left hand, gangrene of the right hand, marked cerebral congestion, cloudy swelling of the kidneys, liver, and heart, and multiple abscesses of the lung and kidneys. Culture of these abscesses showed the presence of *Staphylococcus aureus* and *Streptococcus hemolyticus*.

CASE 7.—L. B., a 6-year-old girl, was admitted with a history of chills and fever for one week. On admission she was markedly delirious. There were numerous purpuric areas on her body. She died the next day. Culture on admission, twenty-four hours before death, showed many colonies of *Streptococcus hemolyticus* and a *Staphylococcus aureus* in the blood.

CASE 8.—E. F., a 4-month-old male infant, was admitted with a history of a hematuria and a loss of weight for a month. After study an operation was performed. The child's course was progressively downhill, and he died a month after admission. The child showed *Staphylococcus aureus* in the blood twice, and a small invasion with *Staphylococcus aureus* and *B. coli* once, following the first cystoscopy.

CASE 9.—I. M., a 13-day-old male child, who was perfectly normal for six days after birth, developed a severe diarrhea on the seventh day. On the eleventh day he was admitted to the pediatric service with dehydration and gastrointestinal intoxication. At this time, he also had a bilateral purulent acute otitis media and a definite rhinopharyngitis. A continuous intravenous solution of glucose and a blood transfusion were administered, but the patient grew steadily worse, and two days later died. A cardiac puncture was done immediately after death, and a culture of the blood showed innumerable colonies of *Streptococcus hemolyticus*, *B. coli*, and a *Staphylococcus aureus*. Autopsy revealed an acute enteritis, purulent otitis media, lobular pneumonia, and cloudy swelling of the viscera.

II. SEPTICEMIA COMPLICATED BY SECONDARY BACTERIEMIA

There were five patients in this group. In three instances the patient first had a *Staphylococcus aureus* sepsis and then developed a hemolytic streptococemia. In one case of *B. coli* septicemia, a secondary invasion by *Streptococcus hemolyticus* occurred. The fifth was a patient who was admitted with hemolytic streptococcus sepsis and later developed *B. coli* septicemia.

In three cases the size of the original invasion was classed as "large," and in two it was designated as "medium." The number of colonies in the secondary invasion was "large" in four instances, and "small" in one.

Four of the five patients in this group were less than 6 weeks old. One was 18 months old. All five were boys. All died.

The incubation period varied from three to fourteen days. The shortest period of hospitalization was twenty-four days, and the longest period of hospitalization was fifty-five days. In three cases there was an afebrile interval between two septic periods. In these it appeared as though the patients were convalescing from the first blood stream invasion when the second invasion began. The duration of the first acute episode was from eleven to sixteen days, and of the second, from seven to eight days.

In three patients an extensive erysipelas or an erysipelas-like eruption heralded the appearance of the secondary streptococcemia. In one, the entire neck was involved. In another, the lesion spread over the entire chest. In the third, there was involvement of both shoulders and the scrotum. We hesitate to designate these diffuse, bright red, indurated skin infections as erysipelas, because in all instances there were large numbers of colonies of *Streptococcus hemolyticus* in the blood. In all of our cases of primary erysipelas, the blood culture was usually sterile or at most an occasional small, transitory invasion was found.

We could not find any valid factor to account for the onset of the secondary infection. Treatment of the original sepsis may have created new foci of infection. In all instances the primary sepsis was treated vigorously with blood transfusions, clyses, infusions, and in one case with staphylococcus toxoid. In addition, suppurative foci were incised. On the other hand, we have 315 cases of sepsis that received similar treatment without developing secondary bacteriemia. The case histories of the five patients in group II follow:

CASE 10.—A. S., a male, 3 weeks old, was admitted with a history of osteomyelitis of the right hip for ten days and of the right knee for two days. On admission he showed a diffuse pustular eruption and evidence of trauma to the scalp from a forceps delivery. Blood culture showed ten colonies of *Staphylococcus aureus* per cubic centimeter of blood. Some skin abscesses formed which required incision and drainage.

Supportive treatment was administered. The temperature subsided gradually and remained normal for a period of two weeks. The number of colonies in the blood stream gradually decreased, and after the third culture the blood was sterile. Toward the end of the third week after admission, there was a sudden elevation to 102° F.; swelling and redness of the left shoulder appeared at the same time. The shoulder was incised on the following day. Instead of a pure culture of *Staphylococcus aureus*, which had previously been found in all cultures of the skin lesions, there was now a mixture of staphylococcus and *Streptococcus hemolyticus*. The temperature, however, remained normal for four days; on the fifth day there was a rise, and the blood culture showed four colonies of *Streptococcus hemolyticus* per cubic centimeter of blood. The temperature continued to increase. Two days later there were 21 colonies of *Streptococcus hemolyticus* per cubic centimeter of blood, and on the tenth day after incision of the shoulder an erysipelas-like rash appeared over the shoulders and scrotum. Two days later the child died.

CASE 11.—B. H., a newborn baby boy, was well until the third day after birth, when he developed slight jaundice, fever, and a moderate diarrhea. On admission to the pediatric service on the sixth day of life, there were 35 colonies of *B. coli* per cubic centimeter; nine days later there was *B. coli* in one broth only. Moderate variations in the extent of invasion continued. One month after admission the culture was sterile and remained so for over a week. During this time the patient's clinical status seemed fair. At the end

of the fifth week there was a sudden rise in temperature to 104° F., and on the same day an erysipelas-like eruption appeared over the child's chest, and *Streptococcus hemolyticus* appeared in two broths. The rash spread, but the blood culture on the next day was still sterile. The child died four days later. Autopsy confirmed the diagnosis of erysipelas.

CASE 12.—N. E., an 18-month-old male baby, was admitted with a history of coryza and generalized anasarca of two weeks' duration. On admission, besides the edema, there was marked abdominal distention. Blood culture showed seven colonies of *Streptococcus hemolyticus* per cubic centimeter. Two days later the blood culture was sterile. On the sixth day an erysipeloid rash appeared over the lower back. The child had a septic temperature during the first two weeks, followed by an afebrile period of twenty days. At the end of that time he suddenly developed fever and diarrhea, and within twenty-four hours, intestinal intoxication. He died three days later. Cardiac puncture immediately after death showed innumerable colonies of *B. coli*.

CASE 13.—F. C., a male, 5 days old, was born at home after a difficult delivery. The infant was cyanotic and dyspneic for two days after birth. On the day of admission he became stuporous and gradually lapsed into coma. On examination a left Erb's palsy and evidence of intracranial injury was found. In addition there was a diffuse induration of the skin of the back. On the eleventh day after admission, the child's temperature became elevated, the edema of the back became red, and a mass appeared on the right buttock. Blood culture showed 20 colonies of *Staphylococcus aureus* per cubic centimeter. Two days later both abscesses were drained. The child's condition, however, did not improve, and six days later he died. Two days before death 50 colonies of hemolytic streptococci per cubic centimeter appeared in the blood.

CASE 14.—V. de P., an 8-day-old male, was admitted with jaundice and fever of a few hours' duration. On admission he was markedly jaundiced and somewhat cyanotic. A mild omphalitis was found. Blood culture showed *Staphylococcus aureus* in both broths. The child received supportive measures, but seven days later he still had 12 colonies of *Staphylococcus hemolyticus* in the blood. During the third week of his stay he developed evidence of a bronchopneumonia, but the blood culture was sterile. After this the course was steadily downhill. He developed diarrhea, and one week later cellulitis appeared at one of the transfusion sites, but this seemed to subside with hot compresses. Five days later an erysipeloid rash appeared on the scrotum and upper thighs. Blood culture showed 25 colonies of hemolytic streptococcus per cubic centimeter. The next day the infant died. Autopsy showed bronchopneumonia, cellulitis of scrotum and thigh, and acute lymphadenitis of nodes around the left common iliac vessels.

III. SPURIOUS MIXED SEPTICEMIA

In this group of patients the clinical features were determined by the primary rather than by the secondary invader.

The secondary invader was one of two types:

- (A) *Streptococcus gamma* or *viridans* present in the blood as a casual invader, with no clinical or bacteriologic significance or
- (B) The second organism was a variant of the first.

The bacteriologic details of group A are shown in Table I.

The details of the cases in group B are indicated in Table II.

Cases 20, 21, and 23 might also be in group A, but we felt that it was more suitable to place them in this group. In Cases 22 and 23 the so-called "degraded" form of the organism appeared in the blood cultures before the "virulent" form.

The clinical significance of these two types of secondary invaders is not known. In the first group (group A) we can see no more significance than we

see in the occasional culture of a gamma streptococcus in the blood of patients with an acute infectious disease. The mutation from the virulent to the non-virulent form of an organism makes the prognosis more favorable (Cases 19, 20, 21), whereas the reverse usually spells a fatal outcome (Cases 22, 23).

TABLE I

CASE NO.	PRIMARY ORGANISM	SIZE OF INVASION	CASUAL INVADER	NO COLONIES	OUTCOME
15	<i>Staphylococcus albus hemolyticus</i>	Medium	<i>Streptococcus gamma</i>	Small	Recovered
16	<i>B. coli</i>	Large	<i>Streptococcus viridans</i>	Small	Died
17	<i>B. coli</i>	Unknown	<i>Streptococcus gamma</i>	Small	Died
18	<i>Staphylococcus</i>	Large	<i>Streptococcus gamma</i>		Died

TABLE II

CASE NO.	PRIMARY ORGANISM	SIZE OF INVASION	SECONDARY INVASION	SIZE OF INVASION	OUTCOME
19	<i>Staphylococcus aureus hemolyticus</i>	Medium	<i>Staphylococcus aureus nonhemolyticus</i>	Medium	Recovered
20	<i>Streptococcus hemolyticus</i>	Small	<i>Streptococcus viridans</i>	Small	Recovered
21	<i>Streptococcus hemolyticus</i>	Medium	<i>Streptococcus gamma</i>	Small	Recovered
22	<i>Streptococcus viridans</i>	Small	<i>Streptococcus hemolyticus</i>	Large	Died
23	<i>Streptococcus viridans</i>	Small	<i>Pneumococcus XX</i>	Medium	Recovered
24	<i>Dysentery-like organism</i>	Unknown	<i>B. coli</i>	Unknown	Died

CONCLUSION AND SUMMARY

In 8 per cent of a total of 320 cases of septicemia, a second organism appeared in the blood stream at some time during the illness. In 3 per cent, two organisms of definite pathogenicity appeared in the same culture. In 1.5 per cent invasion by the second organism appeared as a complication of the original sepsis, often when the first infection seemed to be on the decline. In the remaining cases (3.5 per cent) the second invader seemed to have no clinical or pathologic significance, but appeared merely as a casual invader of the blood stream or as a variant of the first organism.

One might suppose that once the body resistance to blood stream invasion is overcome, any number of organisms could follow the first invader. If we may look upon sepsis as an infectious disease, we see that septicemia is not complicated by a superimposed blood stream invasion any more often than other infectious diseases. It would appear that the immunologic changes which permit the onset of a sepsis are specific for one organism. Invasion by more than one organism

rarely takes place. When it does occur, it is seen only in very young infants and the outcome is invariably fatal.

Two points of special clinical interest are worthy of note. The first is the appearance of an erysipeloid rash when a hemolytic streptococcemia is superimposed on an existing sepsis. The other is the difference in the clinical course in types I and II. In the cases with two organisms in the same blood culture the incubation period was long, followed by a short, acute course terminating rapidly in death. Where the second invasion complicated a primary sepsis, the incubation period was short. The illness was characterized by two septic periods separated by an afebrile period, the second coincidental with the second invasion.

OBSERVATIONS ON THE TOXICITIES AND CHOLERETIC ACTIVITIES OF CERTAIN BILE SALTS*

FRED S. GRODINS, M.S., M.D., A. L. BERMAN, PH.D., M.D., AND
A. C. IVY, PH.D., M.D., CHICAGO, ILL.

IT IS a well-known fact that the toxicity of bile is due to its bile salt content.¹⁻⁶ The choleretic properties of bile salts are also known.⁷⁻¹³ Comparisons of the relative toxicities and choleretic activities of the various bile salts have been limited by the fact that many of them have not been available in pure form. Some of the contradictory results which have been reported may be attributed to the fact that preparations of different degrees of purity have been used. We have recently had available a number of highly purified bile acid preparations and have studied their toxicity and choleretic activity in an attempt to correlate these properties with chemical structure.

METHODS

The toxicities of seven bile salts have been compared by blood pressure studies on anesthetized dogs and by in vitro hemolysis studies on human erythrocytes. The relative choleretic activities have also been studied in the anesthetized dog.

Bile Salt Preparations.—The sodium salts of cholic acid, dehydrodeoxycholic acid, apocholic acid, and deoxycholic acid were prepared by dissolving the pure bile acids† in alcohol, neutralizing with dilute sodium hydroxide to the phenolphthalein end point, evaporating to dryness, and finally dissolving the dry salt in distilled water. Dehydrocholic acid‡ was furnished us as the sodium salt. We have used two different preparations of sodium glycocholate and of sodium taurocholate, one a natural product† and one a synthetic product.§ Aqueous solutions of the natural products were yellow in color whereas the synthetic salts gave clear colorless solutions.

Chemical assays revealed a 56 per cent cholic acid content for the natural taurocholate, corresponding to 71 per cent purity; the synthetic taurocholate assayed 80 per cent cholic acid, corresponding to 100 per cent purity; the synthetic glycocholate assayed 87 per cent cholic acid, corresponding to 97 per cent purity.

Blood Pressure Studies.—Dogs under sodium pentobarbital anesthesia were used. A tracheal cannula was inserted, and the carotid blood pressure was recorded. The common bile duct was cannulated close to the duodenum, and the

‡G. D. Searle & Co., Chicago, Ill.

cystic duct was ligated. The sodium salts of the bile acids in 10 per cent solution were used. All injections were given into the femoral vein at a standard rate (fifteen seconds). The doses arbitrarily chosen were 30 mg. per kilogram, which is the standard intravenous dose of sodium dehydrocholate in man, 10 mg. per kilogram, and 5 mg. per kilogram. Several injections were given to the same animal. At least twenty to thirty minutes were allowed between each injection, which was ample time for the blood pressure to return to normal. The order in which the different salts were given was varied in each animal.

Hemolysis Studies.—Hemolytic activity was studied by the method of Ponder¹⁴ using human cells. Solutions containing 50 mg. of bile salt in 4 c.c. of 0.9 per cent sodium chloride solution were made up. Dilutions of this solution were then prepared: 1:10, 1:100, 1:1,000, etc. One cubic centimeter of standard suspension of human red blood cells was added to 4 c.c. of bile salt solution, and the time for complete hemolysis was noted. The tests were made in a water bath at 38° C.

Choleretic Studies.—The dogs were prepared as described for the blood pressure studies. After a uniform bile flow was established, a control period of thirty minutes to one hour was recorded. Thirty milligrams per kilogram of bile salt in 10 per cent solution was then injected into the femoral vein, and the bile volume was recorded every fifteen minutes until the rate of secretion had returned to the control level.

RESULTS

Blood Pressure Studies.—The averaged results of the blood pressure studies are given in Table I. A 10 mg. per kilogram dose of each of six salts was tested on 10 animals. The 30 mg. per kilogram dose was tested on 10 animals with four salts and on 5 animals with two. Because of the limited supply of sodium taurocholate available, only a single dose, 30 mg. per kilogram, was tested on 6 animals. A 30 mg. per kilogram dose of synthetic sodium glycocholate was tested in 6 experiments on 3 animals. In 4 animals a 5 mg. per kilogram dose of apocholate and deoxycholate was tested.

As indicated in Table I, sodium dehydrocholate was the least toxic and sodium deoxycholate was the most toxic of the seven salts tested. There appears to be little difference between the conjugated salts, cholate, and dehydrodeoxycholate, although the latter seems to be somewhat more toxic. There was no significant difference between the effect of the synthetic and natural preparations of the glycocholate and taurocholate. In 4 animals 5 mg. per kilogram of apocholate produced an average depression of 17 mm. Hg, and deoxycholate produced 21 mm. Hg. These depressions are greater than those produced by twice the dose of the other four salts in which a 10 mg. dose was tested, and by three times the dose of dehydrocholate. In summary, the salts may be divided into three groups. Group I contains only one salt, dehydrocholate, which is by far the least toxic. Group II contains four salts of intermediate toxicity, cholate, two conjugated salts, and dehydrodeoxycholate. Finally, Group III contains the two most toxic salts, apocholate and deoxycholate.

TABLE I
DEPRESSOR ACTION OF BILE SALTS

SALT	DOSE (MG./KG.)	NO. OF DOGS	BLOOD PRESSURE—MM. OF HG.		
			CONTROL	MINIMUM	MILLIMETERS CHANGE
Dehydrocholate	10	10	144	143	- 1
Cholate	10	10	146	138	- 8
Glycocholate (N)	10	10	149	138	-11
Dehydrodeoxycholate	10	10	161	151	-10
Apocholate	10	10	152	124	-28
Deoxycholate	10	10	158	125	-33
Dehydrocholate	30	10	144	134	-10
Cholate	30	10	140	112	-28
Taurocholate (S)	30	3	119	95	-24
Taurocholate (N)	30	3	109	84	-25
Glycocholate (S)	30	3	131	103	-28
		(6 tests)			
Glycocholate (N)	30	10	135	103	-32
Dehydrodeoxycholate	30	10	143	102	-41
Apocholate	30	5	152	87	-65
Deoxycholate	30	5	152	79	-73
Apocholate	5	4	124	107	-17
Deoxycholate	5	4	117	96	-21

Comment.—Selecting cholic acid as the parent compound, the effects of various changes in this basic structure may be examined. Oxidation of the three hydroxyl groups of cholic acid to ketone groups markedly decreases the toxicity. Conjugation of cholic acid with glycine or taurine does not have a marked effect on the toxicity. The removal of the hydroxyl group on C7 of cholic acid very markedly increases toxicity. *Oxidation of the two hydroxyl groups of deoxycholic acid markedly (44 per cent) decreases the toxic properties of the latter compound*, though not so markedly (64 per cent) as the oxidation of cholic acid. Apocholic acid, which differs from deoxycholic only in having one ethylene linkage ($C8 = C9$), has toxic properties similar to those of the saturated substance.

Hemolysis Studies.—Difficulty was experienced in obtaining cell suspensions with uniform properties, even though the blood was always taken from the same person and an exactly similar technique was employed in the preparation. However, although the absolute dilutions did not check exactly with different cell suspensions, the order of hemolytic activity of the different salts tested on the same cell suspension was always the same. On the basis of our results the various salts may be divided into three groups according to their hemolytic activity (Table II).

TABLE II
HEMOLYSIS BY BILE SALTS

Group I —Weakly hemolytic	1. Dehydrocholate
Group II —Moderately hemolytic	1. Synthetic glycocholate
	2. Synthetic taurocholate
	3. Cholate
	4. Dehydrodeoxycholate
Group III—Strongly hemolytic	1. Natural glycocholic
	2. Natural taurocholic
	3. Apocholic
	4. Deoxycholic

Comment.—Oxidation of the three hydroxyl groups of cholic acid decreases the hemolytic activity of this substance. The removal of the OH group on C7 markedly increases the hemolytic activity. The hemolytic properties of deoxycholic acid are decreased by oxidation to the ketoacid. The conflicting results obtained with the conjugated salts are of interest. The synthetic products were only weakly hemolytic, being second only to the dehydrocholate. On the other hand, the natural products were strongly hemolytic. It is probable that impurities (fatty acids) in the natural products were responsible for the discrepancy. If the synthetic products represent the action of the pure salts, then conjugation does not markedly affect the hemolytic properties of cholic acid.

TABLE III
CHOLERETIC EFFECTS OF BILE SALTS
(30 Mg. per kilogram of body weight intravenously)

SALT	NO. OF ANIMALS	BILE VOLUME PER 1 HOUR PERIOD			30 MIN. AFTER INJECTION
		CONTROL*	FIRST HOUR AFTER INJECTION	% CHANGE	
1. Dehydrocholate	5	2.0	13.5	+575	16.8
2. Apocholate	5	2.0	10.0	+400	11.8
3. Deoxycholate	6	2.0	8.9	+345	11.2
4. Cholate	6	2.0	7.3	+265	9.3
5. Dehydrodeoxycholate	5	2.0	6.4	+220	8.3
6. Glycocholate (S)†	6	2.0	6.4	+220	7.2
7. Taurocholate (S)†	9	2.0	5.5	+175	6.9

*In order to illustrate the relative choleretic effects more clearly, all of the volume outputs have been recalculated on the basis of a common control value, i.e., 2 c.c. per hour. The actual control values varied from 1.6 to 2.6 c.c. per hour.

†Sufficient of the natural compound was not available for this study.

The first three salts produced a choleresis lasting somewhat longer than the last four; the choleresis of the last four was completed in one to one and one-half hours.

Choleretic Studies.—The results of the choleretic studies are summarized in Table III. Sodium dehydrocholate is by far the best choleretic. It causes a greater and more prolonged choleresis than any of the other salts studied. Based on the percentage increase in bile output during the first hour after injection, the salts may be grouped as follows in the order of decreasing choleretic properties:

Group I (greatest choleresis)	Dehydrocholate
Group II	Apocholate Deoxycholate
Group III	Cholate Dehydrodeoxycholate Glycocholate (S)
Group IV	Taurocholate (S)

Comment.—Oxidation of the three hydroxyl groups of cholic acid to keto groups markedly increases the choleretic properties. It also appears that removal of the hydroxyl group on C7 of cholic acid increases the choleretic activity somewhat. Preliminary results on chronic biliary fistula dogs¹⁵ do not support this finding. In these experiments the bile salts were given orally, and deoxycholic acid proved to be only about two-thirds as effective a choleretic as

cholic acid. On the other hand, it has been reported that in the anesthetized rabbit, apocholic acid produces a greater choleresis than dehydrocholic acid,¹³ and that both apocholic and deoxycholic acid produce a greater choleresis than cholic acid.¹⁰ The results of recent studies¹⁶ suggest that conjugation suppresses the choloretic effect of the ketocholanic acids. The authors of this report point out the fact that their results do not mean that conjugation of all ketocholanic acids will depress their choloretic activity or that the oxidation of all cholanic acids will give them hydrocholoretic properties.

Our results show that equivalent weights of the conjugated acids are less choloretic than cholic acid. Assuming choleresis to be dependent on cholic acid content, and using the choleresis it caused as a base, one would expect approximately a 213 per cent choleresis with taurocholic acid and a 234 per cent choleresis with glycocholic acid (since our taurocholic acid preparation assayed 80 per cent cholic acid and our glycocholic 87 per cent cholic acid). Our results thus appear to indicate that conjugation with glycine has little effect on the choloretic properties of cholic acid, whereas conjugation with taurine depresses this property. Preliminary results on chronic fistula dogs also appear to indicate that conjugation with taurine depresses the choloretic action of cholic acid.

It is of interest that oxidation of deoxycholic acid to the dehydro form did not in our experience increase the choloretic properties of this substance. Adlersberg and Lustig¹³ quote unpublished work which indicates that dehydrodeoxycholic acid is less toxic and more choloretic than the hydroxyacid. They also report acute experiments in rabbits showing that dehydroapocholic acid is more choloretic than apocholic, and that both the latter acids are better choloretics than dehydrocholic acid. Sobotka¹⁷ states that dehydrodeoxycholic acid is a better choloretic than dehydrocholic. The source of this statement is not given. In our experience, dehydrocholic acid was by far the best choloretic.

DISCUSSION

The literature on the toxicity of bile has been completely reviewed in Horrall's recent book.⁶ Much of the earlier work is of questionable significance because pure substances were not used. To summarize an extensive literature, toxicity studies by various methods (lethal doses in different animals, effect on excised heart and skeletal muscles, effect on the gall bladder) reveal that cholic acid is much less toxic than deoxycholic and that dehydrocholic acid is the least toxic of all. The majority of studies on hemolysis place the order of increasing hemolytic activity as follows: dehydrocholic < cholic < apocholic < deoxycholic. In general, these results are in agreement with our own. It is worthy of note that the relative toxicity, as tested by depression of blood pressure and hemolysis, is practically identical. The structural implications of our results have already been discussed.

The majority of the pertinent literature on choleresis has been cited. Regan and Horrall¹¹ found glycocholic acid to be more toxic and less choloretic than dehydrocholic acid. This is in agreement with our findings.

SUMMARY AND CONCLUSIONS

1. The toxic and choleric properties of seven bile salts have been studied in the dog.
2. Based on depressor and hemolytic activity, dehydrocholate is the least toxic salt, and apocholate and deoxycholate are the most toxic salts. The other four salts form a group of intermediate toxicity.
3. A discrepancy in the hemolytic activity of two different preparations, one synthetic and the other a "natural" but not pure, of the conjugated cholates has been noted. The probable explanation of this fact is discussed.
4. Sodium dehydrocholate, or oxidized cholic acid, or a ketocholic acid, is the most effective choleric, as well as the least toxic. Sodium taurocholate is the least effective. Deoxycholic acid is not a good choleric and is relatively quite toxic.
5. The influence of chemical structure on the toxic and choleric properties of the bile acids has been discussed.

MULTIPLE SERUM ALLERGY IN ATOPIC INDIVIDUALS*

A. IRWIN KLEINMAN, M.D., AND HARRY MARKOW, M.D.
BROOKLYN, N. Y.

WITH the increasing use of animal sera in modern therapeutics, the subject of serum allergy is assuming ever increasing importance. It is not the purpose of this paper to undertake a general discussion of this subject,[†] but rather to determine the frequency with which multiple serum allergy occurs in allergic individuals, and the possible dangers involved when serum of one animal is substituted for that of another without preliminary tests.

Serum allergy may be defined as a state of hypersensitivity to a foreign serum, usually the result of a previous serum injection. In the allergic patient it may be coincident with a sensitiveness to the animal dander which contains also a small amount of serum antigen. The parenteral administration of a foreign serum in atopic persons even in minute quantities, is likely to result in serum reactions. The latter may be of the delayed type—accelerated serum sickness, or the precipitating or immediate reaction. A history of asthmatic attacks when in contact with horses, “horse asthma,” or, for that matter, a history of allergic manifestations when in contact with other animals, increases the possibility of severe or even fatal reactions to a much greater degree. Boughton¹ in 1919 reported a death which resulted from the administration of one minim of horse serum intravenously to a horse asthmatic. Fatal reaction from an intracutaneous test with 0.05 c.c. of horse serum was described by Friedman² in 1935. Lobo³ in 1936 reported a death which resulted from the subcutaneous injection of 5 c.c. of antidysentery serum to a 1-year-old child with “exudative diathesis.” In 1937 Vaughan and Pipes,⁴ in reviewing the literature from 1923 to 1935, found reports of 35 fatalities from serum administrations, 6 of the deaths following intracutaneous tests with undiluted serum. Shock following an intravenous test^{7,†} with a 1:50 dilution of rabbit serum in two allergic individuals was described by Horsfall and his co-workers.⁵

As the reports in the literature deal mostly with horse serum, the question arises whether the dangers involved in its use in allergic persons may be circumvented by substituting a serum obtained from an animal other than the horse. Horsfall and his co-workers,⁵⁻⁷ for example, have advocated the substitution of antipneumococcus serum obtained from the rabbit for that of the horse. They set forth the many desirable advantages that it offers immunologically and also

*From the Allergy Department, Beth El Hospital, Brooklyn.

Received for publication, September 30, 1940.

†For a comprehensive analysis of the literature on serum allergy, the reader is referred to a review by Harten and Walzer, *J. Allergy* 11: 68, 1939.

‡These authors feel that the intravenous test to establish serum sensitivity in allergic persons, because of the possible occurrence of severe immediate serum reactions or even fatalities, is a procedure fraught with much danger and should, therefore, not be used routinely, if at all.

pointed out that a smaller percentage of persons are apt to be sensitive to rabbit serum than to horse serum. That such is the case cannot be denied, considering the fact that immune sera up to recent times have been derived from the horse almost exclusively. One must bear in mind, however, that the occurrence of atopic serum allergy does not necessarily require a previous serum injection, as exposure to the animal dander in allergic persons may sensitize them to the homologous serum as well. That horse dander contains also a small amount of horse serum antigen has been amply demonstrated by the work of Rackemann,⁸ Forster,⁹ Ratner and Gruehl,¹⁰ and Tuft.¹¹ That this is also true of other animal danders may be deduced from the work of Walker,¹² who showed that 70 per cent of his cat dander cases were also allergic to cat serum. These figures indicate an even higher percentage of serum antigen in the danders of these animals than in that of the horse, since he obtained only 22 per cent of horse serum reactions in those allergic to the horse dander.

Simon¹³ in 1934 reported 12 patients whom he skin-tested with 9 mammalian sera and found that 3 of these reacted to all 9 sera, 4 reacted to horse serum plus one or two additional sera, and 5 were sensitive to horse serum alone. As a result of these findings, he concluded that there must be a common serum antigen in all mammalian sera in addition to a species-specific antigen characteristic of each one; and that whereas most people become sensitized to the latter factor, some few become allergic to the common factor. Two of 67 patients with pneumonia reported by Horsfall and his co-workers⁷ were found to be sensitive to horse serum and went into shock after an intravenous test with rabbit serum, thus indicating that they were sensitive to at least two sera.

It appears, therefore, from these observations that there are persons who may be sensitive to more than one serum. Indeed, some probably are sensitive to all mammalian sera. In view of these facts it was our object to investigate: (1) the frequency with which sensitivity occurs in allergic persons to the serum of horse and other animals; (2) the value of the skin and ophthalmic tests in the diagnosis of serum allergy; (3) the relationship between serum and dander allergy; and (4) the comparative incidence of horse serum allergy in allergic persons who previously had received serum injections and in those who had not.

Forty patients from our Allergy Clinic, consisting of hay fever and asthma cases, were tested with 1:100 and 1:10 dilutions of horse, goat,* rabbit,* and sheep serum with the intracutaneous skin and ophthalmic tests, and also with the corresponding danders (Table I). Of these, 3 cases originally reacted to 1:100 dilution of horse serum by the intracutaneous skin test with a four-plus reaction. These cases and any others that reacted to the higher dilution of a serum were, for obvious reasons, not tested with the 1:10 dilution. If the reaction with the 1:100 dilution was three plus or less, a 1:10 dilution of the +

*Rabbit and goat sera were kindly supplied by the Lederle Laboratories.

†The reactions were read after an interval of ten to fifteen minutes, according to the following scheme:

Four plus—large wheal 2 cm. in diameter or
 Three plus—wheal smaller than above, with no
 Two plus—definite wheal smaller than above, *etc.*
 One plus—erythematous flare with slight or no wheal.
 0—no discernible reaction.

¹pseudopodia.

different sera was used for skin testing. On a subsequent visit,* conjunctival tests† were performed with 1:100 dilution of the sera. If the test was positive, the higher concentration was not used. When the opposite was the case, the tests were repeated with the 1:10 dilutions. No more than one conjunctival test was done at one time; the other eye was used as a control. In case of obvious lack of sensitivity more than one serum was used for testing after a proper interval.

Fig. 1.—Case 1. Patient S. B. Direct intracutaneous skin tests with 4 different sera diluted 1:100. Photographed after twenty minutes. All reactions were markedly positive to the 4 sera, showing wheal with pseudopods and area of erythema. *a*, Horse serum 1:100; *b*, goat serum 1:100; *c*, rabbit serum 1:100; *d*, sheep serum 1:100; *e*, control, buffered saline; *f*, control, buffered saline.

Of the 40 allergic individuals studied, 3, or 7.5 per cent, yielded four-plus skin and positive conjunctival reactions to all 4 sera (Table II; Figs. 1 and 2). These 3 cases in addition exhibited systemic reactions besides the marked local reactions. The former consisted of sneezing fits and attacks of asthma which required the administration of epinephrine. One patient (Case 1) also exhibited angioneurotic edema of eyelids and face, and generalized urticaria; another (Case 24) showed four-plus skin reactions to goat and sheep sera, and negative reactions to the other two sera; the ophthalmic reactions were not done due to the patient's failure to return to the clinic. Four patients, or 10 per cent, evidenced four-plus skin reactions to one or more serum, 3 of them also exhibited positive conjunctival tests, 1 was not tested; the remaining 36 cases evidenced skin reactions varying from three to one plus; and none gave a positive eye test. If all degrees of skin reactions are considered, then there were 25 cases who reacted to horse serum, 21 to goat serum, 21 to rabbit serum, and 22 to sheep serum. Completely negative reactions were obtained in the remainder (Table II). The number of four-plus skin reactions obtained by Brown and Sechzer¹⁴

*It was found wise to perform the intracutaneous and ophthalmic tests on different days, since positive reactions to both were followed by constitutional reactions in 3 cases, necessitating the use of adrenalin, and, in one case, the use of aminophyllin also.

†A conjunctival test was considered positive if there occurred a definite redness of the palpebral and bulbar conjunctivae due to the injection of the conjunctival vessels associated with itching and lachrimation within five to ten minutes after the instillation of the test solution into the conjunctival sac. In case of marked reactions systemic manifestations also occurred.

with rabbit serum tests in 101 allergic persons were 2 as compared with 3 such reactions in our series of 40 cases; we obtained 3 positive conjunctival tests to their 1. The discrepancy in these figures may be explained by the fact that these authors tested 101 cases at random, whereas we started with 3 patients who were allergic to horse serum.

Fig. 2.—Case 1. Patient S. B. Positive ophthalmic test of right eye (one drop of 1:100 sheep serum was instilled); left eye control. Photographed after ten minutes. Reaction, however, started in about three minutes. Patient experienced marked itching and also tearing of the eye. Rhinorrhea, sneezing, and choking of the chest with dyspnea also occurred. Adrenalin 1:1,000 locally and subcutaneously had to be administered.

Brief case histories of 5 persons who reacted positively to one or more serum and one or more danders are given.

CASE REPORTS

CASE 1.—S. B., a female stenographer, aged 20 years, had perennial bronchial asthma. She gave no history of allergic symptoms on contact with animals, nor of any previous serum administration. She reacted to all 4 sera both by skin and eye tests. Four-plus skin reactions were also obtained with horse and cat dander and pork, beef, and lamb. There were clinical improvements from the elimination of these foods. She exhibited constitutional reactions following skin tests with all 4 sera, conjunctival test with one of them necessitating the use of adrenalin and aminophyllin for the relief of asthma and angioneurotic edema (Figs. 1 and 2).

CASE 8.—W. G., a male, aged 22 years, waiter at the Hospital, had perennial asthma. He gave a definite history of asthmatic attacks when in proximity to rabbits and when working in a sweater factory. There was no history of any serum injections. He reacted to all 4 sera both by skin and conjunctival tests, and also showed four-plus skin reactions to goat, rabbit, cat and dog epithelia, and also to pork, lamb, beef, and milk. Constitutional reaction resulted from the positive skin and eye tests, necessitating the use of adrenalin.

CASE 15.—S. P., a 14-year-old schoolgirl, had perennial asthma. She had had diphtheria toxin-antitoxin in childhood, but no other sera. She gave no history of any allergic manifestations on contact with animals. Four-plus skin reactions to all 4 sera, as well as positive conjunctival tests, were obtained. The danders of horse, rabbit, cat, and dog, as well as pork, lamb, and beef, yielded four-plus skin reactions. Constitutional reaction resulted from the positive skin and eye tests, necessitating the use of adrenalin.

CASE 24.—P. G., an Austrian female, aged 32 years, domestic, had seasonal hay fever and was asthma sensitive to grasses. She presented no history of any prior serum administration

nor allergy on contact with animals. Goat and sheep sera yielded positive four-plus skin reactions. Horse and rabbit sera yielded negative reactions. The ophthalmic reactions were not done since the patient failed to return. No reactions to the homologous or to other danders were obtained.

CASE 36.—E. G., a female, aged 32 years, housewife, had seasonal hay fever and was asthma sensitive to ragweed and trees. She had diphtheria antitoxin in childhood, but no other sera. She gave no history of allergic symptoms on contact with animals. She had a four-plus skin and positive conjunctival test to horse serum. She did not react to the other sera. She also exhibited a four-plus skin reaction to horse dander but not to other danders.

In studying the case histories of patients who showed positive reactions to serum, it may be noted that they also reacted to one or more animal danders. It has already been mentioned earlier in this paper that animal danders also contain a small amount of the homologous serum antigen. Exposure, therefore, to the animal dander may well sensitize an allergic individual to the serum. This may serve to explain, as brought out by Ratner and Gruehl's¹⁰ experiments on guinea pigs, the existence of allergy to serum in atopic persons in the absence of previous serum injections. Of the 3 patients who evidenced four-plus skin and positive eye reactions to all 4 sera, one (Case 8) reacted with four-plus skin reactions also to goat and rabbit danders; another one (Case 1) evidenced similar reactions to horse dander; another (Case 15) to horse and rabbit danders. The one (Case 24) that reacted only to goat and sheep sera did not exhibit any positive reactions to dander, and the one (Case 36) who was positive to horse serum only also reacted to horse dander. Although the number of cases with positive dander reactions* (4 plus) are too small in this series to warrant arriving at any conclusions, it may nevertheless be of interest to note that in atopic persons who are sensitive to animal danders, there is a tendency for them to be also allergic to the homologous serum. The 4 patients with four-plus reaction to horse epithelium were also positive to the homologous serum by skin and eye tests; one case out of 2 with four-plus reaction to the goat dander was also allergic to the serum; both cases with four-plus reaction to rabbit dander also reacted to the serum. Not one out of 4 positive sheep dander cases reacted to the serum.

Tuft¹⁵ in 1932 in a study of serum allergy after diphtheria toxin-antitoxin administration found that those who gave positive reactions showed a positive family or personal history of allergy in 34 per cent of cases, as compared with 7 per cent in controls. These findings, he states, show that the "allergic constitution is an important factor in predisposing these individuals to acquired serum allergy." He also offers evidence to prove that this may not be mediated through the reagin mechanism. In our group of 40 allergies, as far as could be determined by questioning, only 12 had previously received either diphtheria toxin-antitoxin, or diphtheria or tetanus antitoxin (Table III). Two of this group showed four-plus skin and positive conjunctival reactions to horse serum. Two of the 28 who never had received any serum yielded similar reactions. If all degrees of positive reactions to horse serum are included, then 7, or 58.3 per

*Tests were performed with 0.001 and 0.01 concentrations of dander extract (milligrams of nitrogen per cubic centimeter). In case of four-plus reaction to the former, higher concentration was not tested.

cent, of the 12 cases who previously had received serum, reacted to horse serum, and 18, or 64.5 per cent, of those who had not had any serum previously reacted to it. It appears, therefore, that there is very little difference in reactivity in these two groups. Since the series is small, no conclusions are attempted.

TABLE III

COMPARATIVE INCIDENCE OF POSITIVE SKIN AND CONJUNCTIVAL TESTS IN ALLERGICS WHO HAD PREVIOUSLY RECEIVED HORSE SERUM INJECTIONS WITH THOSE WHO HAD NOT

	NUMBER OF CASES	REACTIONS				
		4+ SKIN AND POSITIVE CON-JUNCTIVAL	3+ SKIN AND NEGATIVE CON-JUNCTIVAL	2+ SKIN AND NEGATIVE CON-JUNCTIVAL	1+ SKIN AND NEGATIVE CON-JUNCTIVAL	NEGATIVE SKIN AND CON-JUNCTIVAL
Those who previously had horse serum injections	12	2	2	1	2	5
Those who never had any serum injections	28	2	0	4	12	10

SUMMARY

1. Four-plus skin and positive conjunctival tests were considered in this study as indicating allergy to serum. On the basis of the 40 allergies tested, 5, or 12.5 per cent, exhibited positive reactions to one or more sera; 4, or 10 per cent, to two or more sera; and 3, or 7.5 per cent, to all 4 sera. If all degrees of reaction are included, then 25 were completely negative to horse serum; 19 to goat and rabbit sera, and 18 to sheep serum.

2. Every case with a four-plus skin reaction to a serum also exhibited a positive conjunctival test, and vice versa. At no time was a positive conjunctival test obtained where the intracutaneous test to the serum was less than four plus.

3. a. Correlation between positive reactions to serum, and the corresponding dander antigen:

- (1) Of the 3 cases that reacted to the 4 sera, one case also reacted to horse dander; one to goat and rabbit dander, and one to horse and rabbit.
- (2) The case that reacted to goat and sheep serum evidenced no positive skin reactions to any danders.
- (3) The case that reacted to horse serum alone also was positive to the corresponding dander.

b. correlation between positive reactions to animal danders, and the corresponding sera:

- (1) Of 4 cases that reacted with a four-plus reaction to horse dander, all 4 also were positive by skin and conjunctival tests to the homologous serum.
- (2) Of 2 cases that evidenced four-plus reaction to goat dander, one reacted to goat serum by skin and eye tests.
- (3) Both cases that reacted with a four-plus reaction to rabbit dander also showed positive skin and eye tests to the serum.
- (4) None of the 4 cases that reacted to sheep dander reacted to the serum. This may indicate that reaction to sheep dander is not very specific, or that there is a relatively low degree of association of sheep dander and sheep serum allergy.
- (5) Twenty-eight, or 70 per cent, of the cases had never received any serum injections, while 12, or 30 per cent, did. There was very little difference noted in the number of positive reactions to horse serum in the two groups. Moreover, there were just as many positive reactions to goat, rabbit, and sheep sera where the question of prior serum injection was not a factor.

CONCLUSIONS

1. Atopic persons may be sensitive to the sera of one or more species of animals.

2. A four-plus skin and conjunctival reaction to a serum should be considered *prima facie* evidence that sensitivity to it exists, and its avoidance or the extreme care in its use is indicated.

3. Sensitivity to an animal dander is coincident in many cases with a sensitivity to the corresponding serum.

4. In our series we found very little difference in the frequency of positive reactions to horse serum in allergic persons who previously had had serum injected (diphtheria and tetanus antitoxin and diphtheria toxin-antitoxin), and in those who had never received any serum. Extreme care should be exercised in the use of therapeutic sera in any allergic patient.

5. In all cases the use of immune sera obtained from any species of animal is not devoid of the possibility of serum reactions. In all circumstances skin and conjunctival tests should be performed before a serum from any animal is injected. The presence of a conjunctival reaction is a danger signal which should not be ignored.

PROTHROMBIN STUDIES USING RUSSELL VIPER VENOM*

II. RELATION OF CLOTTING TIME TO PROTHROMBIN CONCENTRATION IN HUMAN PLASMA

ROBERT C. PAGE, M.D., EDWIN J. DE BEER, PH.D., AND
MARTHA L. ORR, M.S., NEW YORK, N. Y.

THE use of Russell viper venom instead of tissue extract as the source of thromboplastic substance in determining the prothrombin clotting time was reported first by Fullerton,¹ and later by Page and Russell.²

The end point of the test is taken as the number of seconds required for a fibrin web to form when calcium is added to a mixture of oxalated plasma and Russell viper venom. The time (result in seconds) obtained is generally considered to be inversely proportional to the concentration of prothrombin in the plasma. In order to determine the relation of prothrombin concentration to clotting time, using Russell viper venom as the thromboplastic agent, the study outlined here was carried out.

METHOD OF STUDY

Blood of normal persons and of patients attending an outpatient clinic is obtained. Only blood from patients not suspected of having liver damage or a vitamin K deficiency is used. Four and one-half cubic centimeters of venous blood are drawn into a dry syringe and mixed with 10 mg. of potassium oxalate in a centrifuge tube. The blood is centrifuged at 1,500 r.p.m. for five minutes and the oxalated plasma is drawn off. The test is performed as follows: 0.2 c.c. of oxalated plasma is pipetted into a small test tube (75 by 10 mm.) and 0.2 c.c. of Russell viper venom,† 1:10,000 solution, is added. Calcium chloride solution (1.11 Gm. calcium chloride per 100 c.c.), 0.2 c.c., is then added, and the stop watch is started. The tube is agitated for ten to fifteen seconds in a water bath (37.5° C.), then removed and tilted until separate discrete fibrin particles can be seen. The first appearance of the fibrin particles is taken as the end point. The prothrombin clotting time is determined on the undiluted plasma (100 per cent). Then a sample of the 100 per cent plasma is diluted with physiologic saline solution so that it represents 80 per cent plasma, and its prothrombin clotting time is determined. Serial dilutions are made containing,

Fig. 1.—Showing the agreement between the plotted points and the curve calculated from the equation $T = 287.3X^{-0.51}$, where T is the clotting time in seconds and X is the percentage concentration of the plasma. Each plotted point is an average of 26 values.

Fig. 2.—A chart giving the probability that an observed prothrombin clotting time or prothrombin concentration is normal. Case I. When the clotting time has been determined by the method described in this paper, or by some type of Quick's method giving essentially the same results (Page and Russell²), use the left-hand scale and then locate the corresponding point horizontally opposite on the curve. The nearest probability may then be read directly. Case II. When the average normal value has been found by experience to be appreciably different from twenty seconds, express the observed clotting time as a per cent of the average normal value and use the righthand scale. For example, if the average normal value in the experience of the laboratory has been found to be 22.2, and the particular observed value to be 30 (a figure which is about 135 per cent of the normal), the right-hand scale shows that the chances of this value being normal are quite small, i.e., between 1:100 and 1:1,000.

respectively, 60, 40, and 20 per cent of plasma, and the prothrombin clotting time is determined for each dilution. Each test is performed in triplicate, and the average time is taken for the result.

If the oxalated blood is allowed to stand for more than two hours before centrifugation, the prothrombin clotting time is usually increased, but occasionally it is decreased, the latter probably due to hemolysis with release of lecithin. If, on the other hand, the oxalated blood is centrifuged immediately, or at least within an hour, and the separated plasma is allowed to stand at room temperature for one and one-half to five hours, the prothrombin clotting time is usually increased in both the 100 per cent and 20 per cent plasma dilutions. These changes in prothrombin clotting time incident to standing led us to perform the test as soon as possible after the withdrawal of the blood.

RESULTS OF STUDY

The routine was carried out on 26 persons, and the resulting data are summarized in Table I. By extensive statistical treatment, the hyperbola of Fig. 1 was found to fit these data. Quick^{3, 4} reports similar findings for data obtained by his methods.

TABLE I

PROTHROMBIN CLOTTING TIME DATA FOR DIFFERENT CONCENTRATIONS OF PLASMA USING SAMPLES OF BLOOD FROM 26 PATIENTS

	PERCENTAGE				
	100	80	60	40	20
Mean	20.76 sec.	22.81	26.60	33.10	51.36
Maximum	25.0	27.8	33.4	42.2	69.5
Minimum	15.4	16.5	17.0	20.0	40.4
Standard deviation	2.32	2.99	3.80	5.82	8.67

DISCUSSION

What is normal prothrombin clotting time? The question as to whether a particular clotting time is normal or abnormal is of great practical importance, and because of individual variations is difficult to answer. However, by means of Fig. 2* it is possible to estimate what the chances may be that a given high clotting time represents a high normal figure. If the chances are very slight that the high figure is normal, one may then be more certain that the high value is due to abnormal causes. Thus for example, if the clotting time of a patient's plasma is twenty-four seconds (corresponding to a plasma prothrombin concentration of about 70 per cent) should the value be considered a high normal, or does it indicate an abnormal clotting time? Reference to Fig. 2 reveals that the chances of such a clotting time being normal are only 1 to 20, and that the value must be considered on the border line. If the clotting time is twenty-six seconds corresponding to a plasma prothrombin concentration of about 63 per cent, the figure may quite safely be considered abnormal, since the chances are

*Fig. 2 was constructed as follows: All clotting times were expressed as logarithms, since the distribution then appears to be more nearly normal, and the expected mean and the standard deviation were found to be 1.2961 and 0.01955, respectively. Three multiples of the standard deviation (0.0815, 0.1153, and 0.1531) corresponding to the probabilities 0.05, 0.01, and 0.001 were added to the mean. The antilogs of these three sums were found, and the resulting clotting times were marked off on the curve of Fig. 2. The three factors for multiplying the standard deviation may be computed from such tables as Pearl's areas of the normal probability curve or the probit tables of Bliss.⁴

1 to 100 against a normal clotting time being so high. If the clotting time is twenty-eight seconds, the plasma prothrombin concentration is only about 55 per cent, and the certainty that an abnormal condition exists is even greater, since the chances that it might be normal have now dropped to 1:1,000.

It is recognized that the same method of prothrombin determination in the hands of different workers does not always yield identical results. Since insufficient evidence exists as to how close an agreement may be expected between different laboratories, Fig. 2 has been made sufficiently adaptable to take care of a variety of conditions. When the average clotting time differs appreciably from the value reported in this paper, an adjustment may readily be made by expressing the clotting time as per cent of the mean.

Differences in the standard deviation which measures the variability about the mean must also be considered. Table I shows that the unselected data of this study are quite closely grouped about a mean value of about twenty seconds. If the data in question are much more scattered than these, the deviation of any suspected observation from the average normal value must be relatively greater before it can be considered abnormal. To take an extreme case, suppose that the standard deviation is twice as great as that reported in this paper. Then the three clotting times corresponding to chances of 1:20, 1:100, and 1:1,000, would have increased only to twenty-nine, thirty-four, and forty seconds, respectively. If, on the other hand, the standard deviation is less, then smaller deviations of the clotting time from normal would be significant.

SUMMARY

Plasma prothrombin dilution studies, using a modified Quick's method employing Russell viper venom instead of brain substance extract, have been carried out on 26 human beings who were found to be normal by clinical tests.

In our hands, using normal undiluted (100 per cent) human plasma, this test gave an average prothrombin clotting time of 20.6 seconds.

When the normal plasma was diluted with physiologic saline according to the following proportions, the prothrombin clotting time increased as the dilution was increased.

OXALATED PLASMA PER CENT	MEAN PROTHROMBIN CLOTTING TIME SECONDS
100	20.76
80	22.81
60	26.60
40	33.10
20	51.36

Graphs for computing the plasma prothrombin concentration (in terms of percentage of normal) from a known clotting time were worked out and are presented in Figs. 1 and 2.

The probability of an increased prothrombin clotting time being normal was given consideration. If the clotting time increases, the odds that it could still be normal decrease, and a statistical computation of this part of the study has been incorporated into a graph that may be used in connection with any method for determining prothrombin clotting time.

We wish to express our appreciation for the assistance and cooperation of Dr. Louis Bauman in whose laboratory this work was carried out.

THE SIGNIFICANCE OF THE XANTHOPROTEIN REACTION IN RENAL INSUFFICIENCY AND OTHER CLINICAL CONDITIONS*

OSCAR B. RAGINS, M.D., IDA KRAUS, PH.D., AND GEORGE C. COE, M.D.
CHICAGO, ILL.

IN 1939 Kenny and Hubbard¹ reviewed the literature and reported their results based on 46 xanthoprotein determinations performed on 39 patients with renal insufficiency. Among other statements, they concluded that "aside from acute nephritis, the xanthoprotein reaction offers the best index of uremic intoxication and that uremic symptoms in individual cases may not parallel retention of urea nitrogen but rather that of aromatic substances."

The differential diagnosis between uremia and other clinical conditions simulating the uremic state is not always easy, especially so when a patient is seen for the first time in coma or in a comatose state. This is particularly true at the Cook County Hospital where numerous patients in whom early diagnosis is imperative, are brought into the emergency room. Although the blood non-protein nitrogen and creatinine levels are routinely determined on all hospitalized patients, these are time-consuming procedures and not infrequently, therefore, accurate diagnosis must await these laboratory reports.

Impressed by this report and an earlier one by Steen² in which he analyzed 210 tests on blood and body fluids from living patients and from autopsies, we have studied the xanthoprotein reaction in renal insufficiency (uremia) and other clinical conditions in order to determine its efficacy in diagnosis and prognosis in uremia.

In 1924 Becher and his associates³ reported an increase of aromatic substances—an ether-soluble group comprising phenols, cresols, aromatic oxyacids and indoxyl, and a nonether soluble group containing the amino acids, tyrosine, phenylalanine, and tryptophane—in the blood of patients with renal insufficiency. In 1925 Becher and Koch⁴ reported markedly increased xanthoprotein values (80 to 250) in patients with uremia and indicated that uremia was less dependent on retention of nitrogenous products than on that of aromatic sub-

*From the Cook County and Mount Sinai Hospitals, Chicago.
Received for publication, July 14, 1941.

stances, and that phenol poisoning resembled true uremia. Irdelp, Guchan, and Kazin⁵ placed the normal xanthoprotein value between 15 and 35 and showed increased values in all types of renal insufficiency.

In our study we have performed 354 xanthoprotein determinations on 295 patients with various clinical conditions, according to the following technique, which is slightly modified from that originally described by Becher:⁶

To 3 or 4 c.c. of oxalated blood or serum, add an equal volume of 20 per cent trichloroacetic acid and mix thoroughly. Allow to stand for several minutes and filter through a Whatman No. 40 quantitative filter paper. The filtrate must be absolutely clear, since a slight turbidity will obviate the result. If the filtrate is turbid, refilter it using a little pumice or talcum to clarify. To 1 c.c. of the clear filtrate add 1 drop of concentrated sulfuric acid, 0.5 c.c. of concentrated nitric acid, and a glass bead, and boil over a free flame for about a minute. Cool and add drop by drop about 1 c.c. of saturated sodium hydroxide till the mixture is alkaline. A marked golden color is obtained when phenolic bodies are present. A pale straw color is considered a negative test.

Quantitative Expression.—Make all measurements accurately and boil as evenly as possible so as to avoid excessive evaporation. Compare the color of the final mixture with a standard 0.3874 per cent solution of potassium dichromate. Prepare a series of standards as shown in Table I.

TABLE I

NO.	K ₂ Cr ₂ O ₇ 0.3874%	WATER	DILUTION	XANTHOPROTEIN NUMBER
I	0.1 c.c.	0.9 c.c.	1:10	100
II	0.1 c.c.	1.9 c.c.	1:20	50
III	0.1 c.c.	2.9 c.c.	1:30	33½
IV	0.1 c.c.	3.9 c.c.	1:40	25
V	0.1 c.c.	4.9 c.c.	1:50	20

Compare the unknown in the tube macroscopically with the diluted standards or in a colorimeter. Thus, if the unknown solution matches standard No. II, the xanthoprotein number is 50; the colorimetric readings would be

$$\frac{\text{Standard set at } 10}{\text{Unknown reads } 19.5} \times 0.1 \times 1,000 = 50+.$$

Since normal equals 15-35, macroscopic comparison was considered sufficiently accurate.

RESULTS

Renal Insufficiency (Uremia).—Sixty-four xanthoprotein determinations were performed on 36 patients with uremia. Of these, 34 showed a rise in xanthoprotein values above 60, associated with a uremic rise in nitrogenous retention (i.e., 90 mg. nonprotein nitrogen per 100 c.c. of blood or higher), although the rise in the xanthoprotein reaction did not always correspond in degree to the rise in the blood nonprotein nitrogen level.

Xanthoprotein values ranged from 62 to 460, and the nitrogenous retention from 37 to 250 mg. per 100 c.c. In two cases the xanthoprotein values were below 60, while the blood nitrogenous level was above 90, i.e., of uremic

nature. Conversely, three cases showed marked xanthoprotein elevations (125, 167, and 70, respectively), while the nonprotein nitrogen level was only 60, 64, and 37, respectively. In only two of the 36 cases, therefore, the nonprotein nitrogen determination was of greater significance in diagnosing uremia than was the xanthoprotein reaction, whereas in three cases the reverse was true.

All but two of these patients died in uremia. In one patient repeated tests indicated a decreasing xanthoprotein value, although the nonprotein nitrogen remained elevated, and he was subsequently discharged; the other patient had elevated xanthoprotein and nonprotein nitrogen values, but left the hospital before repeat studies could be performed. Of the 34 patients who died, two had xanthoprotein values below 50. In one patient in whom 12 xanthoprotein determinations were performed over a period of several months, the highest value was 50, although nonprotein nitrogen values ranged from 93 to 212 mg. per 100 c.c.; in the second patient the xanthoprotein value was 35, and the nonprotein nitrogen was 239.

Six patients with no clinical evidence of uremia showed xanthoprotein reactions over 60: one patient each with nephrosclerosis, nephrosis, rheumatic heart disease, lysol poisoning, diabetic gangrene, and chronic nephritis. All were discharged. The patient with lysol poisoning presented a xanthoprotein value of 325, and a nonprotein nitrogen value of 41. He was discharged before repeat studies were made. By way of contrast another patient with lysol poisoning was admitted, but his xanthoprotein reaction was only 42. The difference of these values in two similar conditions may, we believe, be explained by the differences in time at which blood was secured for this study. Thus, the first patient was hospitalized within several hours of attempted suicide, and blood was obtained shortly thereafter at a time when the blood serum contained considerable amounts of phenol bodies; whereas in the second patient blood was not obtained until several days after hospitalization, at a time when the patient was convalescing and his blood serum apparently was relatively free of phenol bodies.

Cerebral Conditions.—Twenty-two xanthoprotein determinations were performed on 21 patients with various cerebral conditions, including seven patients with hypertensive encephalopathy and 10 with cerebral vascular accidents. In the seven patients with hypertensive encephalopathy the nonprotein nitrogen was elevated, at times markedly so, but in none was the xanthoprotein reaction persistently or markedly increased. In only one patient did the xanthoprotein value reach 50, but on repeating the test it promptly fell to 20. In the 10 patients with cerebral vascular accidents the xanthoprotein reaction was low, despite the fact that the nonprotein nitrogen was elevated in all and markedly elevated in three.

Nephritides.—Excluding the patients with uremia, 30 xanthoprotein reactions were studied on 22 patients with acute and chronic renal pathology. In three patients the xanthoprotein value was elevated beyond 60, but these left the hospital before repeated studies could be done. In the remainder the xanthoprotein reaction was not significantly elevated, although nonprotein nitrogen

levels were very high in many instances. None of the nine patients with acute nephritis showed significantly increased xanthoprotein values, the highest being 31.

Nine xanthoprotein studies were carried out on seven patients with genitourinary conditions, excluding nephritis. In none was the xanthoprotein value significantly elevated, although in two patients with prostate pathology and urinary retention, the nonprotein nitrogen was markedly increased and impending uremia was suspected.

Cardiac Conditions.—Ninety-six xanthoprotein reactions were studied in 81 patients with cardiac disease complicated by cardiac failure. In only one patient was the reaction higher than 60. In two it was over 50, and in five it reached 50. The remainder were below 50. Six patients had xanthoprotein values of zero; in two of these patients the nonprotein nitrogen was markedly elevated, being 125 and 154, respectively.

Gastrointestinal Conditions.—Forty-six xanthoprotein reactions were performed on 43 patients with various gastrointestinal conditions, including 20 patients with carcinoma and marked emaciation and 13 with peptic ulcers, most of which demonstrated active bleeding. In no instance was the xanthoprotein reaction elevated beyond 50, the great majority of reactions being below 20. In 10 the nonprotein nitrogen was markedly elevated.

Pulmonary Conditions.—Fifty-two determinations were performed on 52 patients, mainly with pulmonary tuberculosis or pneumonia, and nothing significant was revealed. The highest value was 41, most values being 20 or lower. Many of these patients had moderately increased nonprotein nitrogen levels and several showed marked increases.

Miscellaneous Conditions.—Thirty-five xanthoprotein reactions were determined on 33 patients with various clinical conditions (alkalosis, alcoholism, arthritis, avitaminosis, pernicious anemia, etc.) not previously included. With exception of the patients with lysol poisoning and diabetic gangrene previously referred to, none showed significant xanthoprotein elevations, although in seven the nonprotein nitrogen was markedly increased.

Included are three patients with coma of undetermined origin. In none was the xanthoprotein or nonprotein nitrogen significantly increased. Five patients had diabetes mellitus, and nothing of significance could be determined from the xanthoprotein reactions.

SUMMARY AND CONCLUSIONS

1. Although the range of normal values of the xanthoprotein reaction is accepted as 15 to 35, our study indicates that a more correct normal range is 0 to 50. Xanthoprotein values over 60 should be considered abnormal in all conditions.

2. Our data indicate that the only specific condition with significantly increased xanthoprotein values is uremia, although lysol poisoning must be kept in mind as a possibility.

3. As an indicator of impending or true uremia, the xanthoprotein reaction seems to be as accurate as the level of nitrogenous retention in the blood. Thus, in our series the xanthoprotein reaction was an accurate indicator in 94.4 per

cent of cases, whereas the blood nonprotein nitrogen level was significantly elevated in 91.6 per cent. A low xanthoprotein reaction does not always rule out uremia (5.5 per cent of uremia cases) nor does a high value invariably mean uremia.

4. The xanthoprotein value does not in all instances prognosticate the course of the patient with uremia, although with one exception all those with uremia whose xanthoprotein reactions were 100 or over died. Conversely, low xanthoprotein values do not preclude a fatal termination of uremia.

5. With the exception of those cases of uremia in which both the xanthoprotein and blood nonprotein nitrogen were definitely elevated, there was no consistent correlation between the xanthoprotein reaction and the level of blood nitrogenous retention.

6. The xanthoprotein reaction is valuable in differentiating cerebral conditions simulating uremia (pseudo-uremia) from true uremia. This is particularly evident in studying patients with hypertensive encephalopathy in whom no instances of elevated xanthoprotein values were noted despite moderate elevation of nonprotein nitrogen in many instances.

7. A low xanthoprotein value is significant in cases of extrarenal azotemia as occurs in dehydration states, following hemorrhage into the gastrointestinal tract, etc.

8. Although the xanthoprotein reaction has some limitations, it is an excellent supplementary test in the study of uremia, suspect uremia, pseudo-uremia, coma, and nephritis. It consumes little time, is simple to perform, and is inexpensive.

THE EFFECT OF ANAPHYLACTIC SHOCK UPON BLOOD POTASSIUM AND CONCENTRATION*

LAURANCE W. KINSELL, M.D.,† AND RAYMUND L. ZWEMER, PH.D.
NEW YORK, N. Y.

CONFLICTING reports relative to the results obtained following employment of potassium salts in allergic conditions¹⁻⁴ and the apparent lack of an adequate rationale for such a procedure on the basis of experimental blood potassium findings⁵⁻⁷ led us to further investigate the subject from an experimental standpoint.

The present experiments were designed to correlate the blood picture with the symptoms manifested in the animals rather than with the sensitizing dose, time intervals, or shock dose. This will be made clear in the presentation of our results, which show the effects of rapidly and slowly fatal anaphylactic shock on potassium, relative red blood cell volume, and plasma specific gravity.

MATERIALS AND METHODS

Guinea pigs, weighing from 250 to 400 Gm., were used in this work. Blood obtained directly from the heart at various time intervals was drawn into a 2 c.c. tuberculin syringe, which contained a small amount of dry heparin (Connaught Laboratories, Toronto). Some of the heparinized blood was run immediately into a heavy wall 1 mm. capillary tube, 10 cm. long, which served as a hematocrit tube. Both the syringe and the tube were closed at both ends with broad rubber bands and centrifuged for fifteen minutes at 3,000 r.p.m. The hematocrit (relative red blood cell volume) was then read off directly in per cent by placing it on a millimeter scale.

The supernatant plasma in the syringe was used for both potassium and plasma specific gravity determinations. Potassium was determined in duplicate on 0.2 c.c. by the method of Truszkowski and Zwemer.⁸ Plasma specific gravity was measured by the technique of Barbour and Hamilton,⁹ and the proteins were calculated by the formula of Weech and co-workers.¹⁰

EXPERIMENTAL

Except for two groups of the controls, all animals were sensitized with 0.25 c.c. of horse serum. A second dose of horse serum was administered one to four weeks later by the intraperitoneal route. The "shock" animals fell into three clinical groups: (a) those that showed no evidence or only questionable evidence of shock (Table I); (b) those that died of anaphylactic shock after a period of

*Death occurred within one hour.

three or more hours (Table II, Graph 4); and (c) those that went into shock and were dead within an hour (Table III, Graph 2). The control series were of four types: (a) three animals sensitized but not shocked, and bled rapidly at intervals corresponding to those undergoing intense shock, one of which is shown

Graphs 1 and 2.—Note that potassium rise in shocked animal is out of proportion to hemo-concentration.

H = hematocrit (packed red blood cell volume per cent).

P = plasma proteins (grams per 100 c.c. as calculated from plasma specific gravity).

K = potassium (milligrams per 100 c.c. of plasma).

Graphs 3 and 4.—Note the steady rise in plasma potassium despite some hemodilution.

in Graph 1; (b) three bled at less frequent intervals which corresponded to slow shock (example in Graph 3); (c) three guinea pigs given large amounts of horse serum without previous sensitization (example in Graph 6); and (d) three controls which had received no injections of any kind and were used to check the effects of blood loss and accuracy of technique (Table IV, Graph 5).

Animals in which anaphylactic shock of rapid onset and marked intensity was produced had a pronounced elevation in plasma potassium which was greater than could be accounted for by the hemoconcentration as measured by red blood cell volume and plasma protein. This was in contrast to the control group which with equally rapid sampling showed hemodilution, lowered plasma protein and, in some cases, a lowered potassium. The changes were roughly proportional to the amount of blood lost by sampling; this blood loss is an important factor in increasing the severity of anaphylaxis in small animals.¹¹

Graphs 5 and 6.—Note the constancy of plasma potassium despite hemodilution resulting from bleeding.

Examples from the significant groups are given in Graphs 1 to 6, and demonstrate quite clearly the effect of anaphylactic shock on the three blood constituents studied. If one compares Graphs 1 with 2, the difference between the shocked and unshocked animals, in so far as plasma potassium is concerned, is quite striking. The same may be said regarding Graphs 3 and 4, the sensitized unshocked animal showing essentially only those changes which may be attributed to blood loss, whereas the shocked animal shows a steadily rising plasma potassium level.

Also, if one compares all the graphs of animals in the control groups (Graphs 1, 3, 5, 6), the general similarity is apparent.

DISCUSSION

A rise in plasma potassium has been shown to be a feature of anaphylactic shock,^{5-7, 12} of neurogenic and traumatic shock,^{13, 14} and of acute allergic reactions.¹⁵ Our results confirm the plasma potassium rise during the course of anaphylactic shock and show it to be definitely out of proportion to the degree of hemoconcentration and increased plasma density.

The findings in regard to changes in blood concentration are confirmatory of the work of Petersen and Levinson,¹⁶ of Simonds,¹⁷ and of Manwaring and

others,¹⁸⁻²¹ most of whom ascribe these changes to disturbances of endothelial permeability occurring during the course of the anaphylactic reaction.

Black and Kemp²² reported a consistent increase in plasma density during the course of anaphylactic shock in guinea pigs. Our findings do not agree, but the time factor, or the amount of blood taken, may explain this apparent contradiction. Other authors report a lack of constant variation in total protein during the course of anaphylactic shock, but note consistent shifts in the albumin-globulin ratio and in fibrin values.²³⁻²⁵

The mechanism of the potassium rise still remains to be demonstrated. Since potassium is the principal intracellular base, as contrasted to sodium, which is the essential basic ion of plasma and interstitial fluid, it seems reasonable to assume that an increase of plasma potassium represents a loss of potassium by cells due to either a change in cell membrane permeability or a disruption in the hypothetical intracellular potassium colloid complex, or both.

Since it has been shown that injections of potassium salts are capable of producing many symptoms of shock,^{6, 27} it seems probable that the increase in plasma potassium, occurring during the course of anaphylactic shock, accounts in some measure for the symptoms which are characteristic of this condition. In view of the close relationship between anaphylaxis and allergy, these findings suggest that the use of large amounts of potassium in allergic conditions is contra-indicated rather than indicated.

SUMMARY

1. Thirty-four guinea pigs were used to determine the effect of anaphylactic shock upon plasma potassium and blood concentration in terms of plasma protein and red blood cell volume per cent.

2. A constant rise in plasma potassium was demonstrated, together with a fairly constant hemoconcentration in terms of red blood cell volume per cent. The potassium rise was relatively much greater than the degree of hemoconcentration and was roughly proportional in degree to the severity of shock. No constant change in plasma protein was demonstrable.

THE CHEMISTRY OF INFECTIOUS DISEASES*

III. POLAROGRAPHIC STUDIES OF THE BEHAVIOR OF NORMAL AND PNEUMOCOCCUS INFECTED DOG SERA TOWARD DENATURATION AGENTS AND ENZYMES

M. L. CROSSLEY, PH.D., R. H. KIENLE, PH.D., BRUNO VASSEL, PH.D. AND
G. L. CHRISTOPHER, PH.D., STAMFORD, CONN.

VERY little information is available on the low molecular weight protein derivatives of serum. Lack of convenient methods of handling proteoses, peptones, and polypeptides is responsible for their neglect in studies of protein metabolism.

The lower derivatives (peptones and polypeptides) are not precipitated by salting-out, and are soluble in trichloroacetic and sulfosalicylic acids, but the addition of tungstic or phosphotungstic acid to a sulfosalicylic acid filtrate of serum will give a voluminous precipitate.

It is not known whether the serum protein derivatives of low molecular weight possess any physiologic activity of their own. Recent evidence indicates, however, that the peptone fraction† of blood serum may play a part in health and disease. It has been demonstrated recently¹ that during experimental type I pneumonia in dogs this peptone fraction greatly increases and remains abnormally high long after clinical evidences of infection have disappeared (fever, complete resolution of the congested areas of the lung as shown by x-ray, and the physical well-being of the animal). A positive polarographic cancer reaction according to Brdicka's technique² probably also depends upon the relative amounts of serum peptones.

The abnormal increase in the peptone fraction of the blood during pneumococcal infection may be only a reflection of a general increased metabolism, possibly associated with fever, or it may be concerned with the catabolism of the proteins at the site of infection. These two possibilities as to the probable source of the increased peptone fraction during infections are under investigation. However, there is another possible explanation. If one or more of the serum proteins should lose their normal stability under the stress imposed upon the organism by the invading microorganism, an abnormal tendency to disintegrate may occur. Certain facts suggest that this might actually take place, and this paper deals with the results of the investigation.

*From the Research Laboratories of the American Cyanamid Co., Stamford, Conn.

A report of this work was presented at the Thirty-Fifth Annual Meeting of the American Society of Biological Chemists, Chicago, Ill., April 15 to 19, 1941.

Received for publication, July 30, 1941.

†Peptone fraction will be defined as that part of blood serum which is responsible for the typical polarographic protein wave in 0.5% NH_4Cl -buffer after precipitation of the proteins by the sulfosalicylic acid.

EXPERIMENTAL

The stability of dog sera toward denaturation and enzymatic hydrolysis before and after experimental type I pneumococcus infection was determined polarographically by comparing the relative rates at which the polarographic wave heights of normal and of infected sera changed during denaturation. Preliminary experiments with urea, guanidine hydrochloride, alkali, and wetting agents showed that 8 M concentrations of the first two denaturing agents inhibited the formation of the typical polarographic wave to such an extent as to preclude their use in this study, while 1 N potassium hydroxide and Aerosol OT gave satisfactory results with the polarograph.

The dogs used in this study were normal, adult mongrels, weighing 34 to 48 pounds, which had lived in our kennel for at least five weeks prior to infection. Diet, care, the method of blood sampling, and the mode of infection with type I pneumococci have been described previously.¹ Denaturation of the sera was obtained by the addition of 10 c.c. of 1 N potassium hydroxide (or 10 c.c. 0.025 M Aerosol OT) to 4.0 c.c. of serum at room temperature. After various intervals, 1.4 c.c. of the mixture were added to 1 c.c. of 20 per cent sulfosalicylic acid and filtered after standing for five minutes. One-half cubic centimeter of the filtrate was electrolyzed in 5 c.c. of the previously described cobaltic ammonium chloride buffer⁴ at 1/100 sensitivity of the galvanometer. The zero time of action was obtained by adding 2 c.c. of a 1:1 mixture of 1 N potassium hydroxide and 20 per cent sulfosalicylic acid directly to 0.4 c.c. of serum, filtering after five minutes' standing, and treating 0.5 c.c. of the filtrate as described above. The conditions of the enzymatic hydrolysis experiments were so chosen that just enough enzyme was present to insure a polarographically measurable digestion under optimum conditions of pH and temperature without having the waves produced by the enzymes themselves mask those produced by the partially digested proteins. The following procedure was finally adopted: 2 c.c. of 10 mg. per cent pepsin (Difco, spongy granular 1:3,000) in 1 N hydrochloric acid were added to 10 c.c. of either normal or infected serum. After a definite period of incubation at 39° to 40° C., 0.48 c.c. of the solution was withdrawn, added to 2 c.c. of 1:1 mixture of 1 N potassium hydroxide and 20 per cent sulfosalicylic acid. After standing for five minutes the solution was filtered. One-half cubic centimeter of the filtrate was analyzed polarographically in 5 c.c. of the cobaltic ammonium chloride buffer with the galvanometer sensitivity set at 1/100. For the tryptic digestion, 8 c.c. of serum were added to 2 c.c. of a 1 per cent trypsin (Difco, 1:110) solution in M/15 phosphate buffer at pH 8. Otherwise the procedure outlined for the peptic digestion was followed, except that 0.5 c.c. of the digestion mixture was added to 2 c.c. of the potassium-sulfosalicylate instead of 0.48 c.c.

All polarograms are self-recorded photographs of the galvanometer deflection. The increase in galvanometer deflection between -0.9 volts and the minimum of the double wave (-1.65 volts) determines the wave height. Any change from the normal is interpreted as being due to concentration changes in polarographic active groups of the peptone fraction of the serum after infection.

The rate at which the wave height increased, above that given by normal serum, by such criteria, would be indicative of an increased rate of denaturation of the serum proteins after infection.

RESULTS

Alkaline Denaturation.—Two typical sets of polarographic recordings of the peptone fractions from alkali-treated dog sera are reproduced in Fig. 1. Curve I, Fig. 1, represents the polarograms obtained from the filtrates of a normal dog serum, while curve II corresponds to that of the serum from the same dog after a mild attack of experimental pneumococcal pneumonia. The severity of infection in all cases is judged by fever, lung congestion as shown by x-ray, and by the general appearance of the animal. Upon the addition of

Fig. 1.—Polarograms and nitrogen values of the serum peptone fraction of alkali-denatured dog sera before (I and III) and after (II and IV) type I pneumococcus infection.

alkali to normal serum, a decrease in wave height occurs in the sulfosalicylic acid-soluble serum fraction during the first five to ten minutes of alkali contact, followed by a rise until a fairly constant wave height is reached at sixty minutes (curve I). Further contact with alkali tends to destroy the double wave, a single wave appearing instead after the 150th to 240th minute. Denaturation of the serum from the same dog after infection (curve II) follows an entirely different course. A rise in wave height occurs during the first five to ten minutes of alkali contact, followed thereafter by a fall to near the original level of the untreated serum (zero time) which, incidentally, is also approximately that obtained from normal serum after sixty minutes' denaturation. The two polarographic denaturation curves are thus entirely different from each other.

Wherever the peptone fraction of normal serum shows a rise in wave height, the corresponding one from the infected serum decreases, and vice versa. There exists still a further difference in the polarograms of the two types of sera. The change from a double wave to a single wave occurs much sooner when the serum from an infected dog is denatured. Depending upon the severity of infection, this change in the structure of the polarograms has appeared as early as forty-five minutes after alkali addition, and always after sixty to one hundred and five minutes, while normal serum never showed the disappearance of the double wave prior to one hundred and fifty minutes of alkali contact.

If the assumption is correct that an alteration in the structure of the serum proteins occurs during infection and is responsible for the observed differences in wave heights during the early, and again in the late periods of alkali contact, then it should follow that the sudden rise in wave height during the first five to ten minutes after potassium hydroxide addition should be most pronounced in cases of severe infections, and less so during the early periods of pneumococcal invasion, when lung inflammation is still restricted. To test this, the spreading of the infection in the lungs was followed by x-ray, and blood samples were drawn at various stages of infection, the serum was denatured as described, and the wave heights of the peptone-polarograms were plotted against time of alkali content. In this manner a series of denaturation curves are obtained (Fig. 2) which fully substantiate the original assumption. The more severe the infection, the greater and more abrupt is the initial rise in wave height, while the polarograms of the normal serum are again entirely opposite. The zero time values in Fig. 2 express, in terms of polarographic wave heights, the pre-existing concentrations of peptone material of the sera prior to denaturation and confirm our previous observations¹ that an increase in the serum-peptone fraction takes place during pneumonia. Interestingly enough, the blood sample drawn twenty-four hours after infection still exhibits a decrease in wave height during the first ten minutes after alkali addition, although it is not as pronounced as for normal serum, while its zero time value demonstrates that an accumulation of peptone material already has begun.

In polarography, changes in wave height merely indicate that concentration changes have taken place in the material which are responsible for the wave. Under our experimental conditions only cystine-containing proteins will give the wave. If the peptones which accumulate during pneumonia, and which are split off from the serum proteins by alkaline denaturation always possess the same average cystine composition, then the nitrogen content of the peptone fraction should fluctuate in a similar manner to that of the corresponding polarograms. Micro-Kjeldahl nitrogens were, therefore, run on some of the peptone fractions at various time intervals of alkaline denaturation, the peptone nitrogen being determined as the difference between the nitrogen value after sulfosalicylic acid and after tungstic acid precipitation of the serum. Curves III and IV in Fig. 1 are graphs of such analyses performed on the serum filtrates which correspond to the polarographic curves I and II of Fig. 1, respectively. It is evident from an inspection of curves II and IV that the peptone fraction of the infected serum (curve IV), as expected, contains more peptone nitrogen

throughout the entire denaturation range than the normal one. Entirely unexpected were the findings that the nitrogen of both the normal and the infected serum filtrates decreased during the first twenty minutes of alkali contact, and then increased thereafter until, after sixty minutes, approximately the initial values were obtained. The changes in peptone nitrogen of normal denatured serum thus ran roughly parallel to those in polarographic wave height. However, this relationship does not hold for those from infected serum. The possible significance of this discrepancy will be discussed later, but it should be pointed out that a direct dependency of wave height to peptone concentration can be readily demonstrated. If, for instance, the observed lower wave height of normal, undenatured serum (i.e., zero times in Figs. 1 and 2) is due to less peptone material than is found in an equal volume of untreated serum of the

Fig. 2.—The influence of pneumococcus infection upon the characteristics of normal serum-peptone curves during alkaline denaturation.

same dog after infection, then it should be possible to match the waves obtained from the latter by merely increasing the amounts of the former. The results of such experiments are shown in Fig. 3. Each polarogram in the upper row was obtained by electrolyzing 0.5 c.c. of serum filtrate (equivalent to 0.083 c.c. of original serum), the blood of which was drawn at various stages of infection. The polarograms of the lower row were obtained from normal serum only, except that the serum concentrations were increased above 0.083 c.c. in such manner that each wave matched in height one of the current-voltage curves of the infected sera. It is evident that the polarograms due to 0.100 c.c., 0.133 c.c., 0.166 c.c., and 0.199 c.c. of normal serum are identical, within the error of the method, with those from 0.083 c.c. of sera drawn from the same dog, twenty-four, forty-two, forty-eight, and ninety hours after infection. Similarly, normal and infected peptone polarograms of denatured sera can be matched, either by increasing the concentration of the former or by decreasing that of the latter.

When different denatured sera are compared, the length of time during which the alkali acts must be the same, since alkali contact eventually causes all peptone polarograms, whether obtained from normal or from infected sera, to lose their double wave. The sera from which the curves in Fig. 4 were obtained were consequently denatured in each case for forty-five minutes with 1 N potassium hydroxide. The infected serum was drawn from the same animal during the

Fig. 3.—The effect of concentration of undenatured serum filtrates from normal and infected dogs upon the polarographic wave height.

course of an infection of medium severity. In order to match the polarograms from 0.061 c.c., 0.083 c.c., 0.122 c.c., 0.163 c.c., and 0.204 c.c. of normal, denatured serum, filtrates containing 0.016 c.c., 0.033 c.c., 0.049 c.c., 0.083 c.c., and 0.098 c.c. of infected serum, respectively, were required. The double wave begins to straighten out when the peptone fraction from 0.163 c.c. of normal or

0.083 c.c. of abnormal serum is electrolyzed, and it disappears completely, in favor of a single wave, when the concentrations of normal and infected serum reach 0.204 c.c. and 0.098 c.c., respectively. These experiments (Figs. 3 and 4) clearly show: (1) that wave height differences in the polarograms of the peptone fraction from dog sera, before and after pneumococcal infection, reflect concentration changes in the polarographically active principle, both for untreated as well as for denatured sera; (2) that, within the limits of concentrations studied here, no alteration in the structure of the polarographic double wave occurs with increasing concentrations of peptone material from untreated serum, but that alkali-denatured serum reaches a limit in concentration above which the double wave changes over to a single wave; (3) that the disappearance of the double wave occurs at considerably lower serum concentrations of infected serum than of normal serum.

Wetting Agents.—Alkaline denaturation at room temperature unquestionably produces more than one change in the structure of a protein molecule. Rupture of secondary linkages, partial hydrolysis of peptide bonds, and a breakdown of disulfides undoubtedly occur. Denaturation by wetting agents, such as Aerosol OT, Duponol PC, Duponol 80, and others³ probably proceeds to a much more limited extent, possibly involving only the liberation of sulfhydryl groups from cystine. Since the polarographic protein wave is supposedly given by -SH-protein as well as by -S-S-protein groups, a preliminary change of the oxidized form to the reduced form by wetting agents should not increase the polarographic wave height, unless a liberation of previously unavailable thiol groups had occurred. If cyclic sulfur compounds of the thiazoline type are part of a protein molecule,⁴ a liberation of new thiol groups by the action of alkali is conceivable and would at least partially account for the increase in polarographic active groups. No information as to the action of wetting agents on these heterocycles is available. It is, however, unlikely that the wetting agents would liberate thiol groups from thiazolines. When the influence of Aerosol OT on serum was studied, it was found that the polarographic peptone wave, even after twenty-four hours of Aerosol OT contact, was identical with that of the same serum at zero time of Aerosol OT action. This was true for normal serum as well as for the serum of the same dog after a severe pneumococcal infection, although the relative heights of the two sera naturally differed, that from normal serum being the lower.

Enzymes.—The observed differences in the behavior of normal and of infected sera toward alkali, and the consequent belief that an alteration in the chemical structure of the proteins had occurred during infection, prompted us to investigate their enzymatic hydrolysis. It was hoped that pepsin and trypsin would digest normal serum proteins at a rate measurably different from that of infected serum; however, no differences were observed. Consequently, only the digestion polarograms of normal serum are shown in Fig. 5, where curve I represents the peptic digestion and curve II the tryptic one. The first current-voltage curve in each series is that of the blank, obtained by substituting saline for the serum. Its wave height must be subtracted from the serum-digestion polarograms if quantitative comparisons are to be made. Qualitatively, it is

When different denatured sera are compared, the length of time during which the alkali acts must be the same, since alkali contact eventually causes all peptone polarograms, whether obtained from normal or from infected sera, to lose their double wave. The sera from which the curves in Fig. 4 were obtained were consequently denatured in each case for forty-five minutes with 1 N potassium hydroxide. The infected serum was drawn from the same animal during the

course of an infection of medium severity. In order to match the polarograms from 0.061 c.c., 0.083 c.c., 0.122 c.c., 0.163 c.c., and 0.204 c.c. of normal, denatured serum, filtrates containing 0.016 c.c., 0.033 c.c., 0.049 c.c., 0.083 c.c., and 0.098 c.c. of infected serum, respectively, were required. The double wave begins to straighten out when the peptone fraction from 0.163 c.c. of normal or

0.083 c.c. of abnormal serum is electrolyzed, and it disappears completely, in favor of a single wave, when the concentrations of normal and infected serum reach 0.204 c.c. and 0.098 c.c., respectively. These experiments (Figs. 3 and 4) clearly show: (1) that wave height differences in the polarograms of the peptone fraction from dog sera, before and after pneumococcal infection, reflect concentration changes in the polarographically active principle, both for untreated as well as for denatured sera; (2) that, within the limits of concentrations studied here, no alteration in the structure of the polarographic double wave occurs with increasing concentrations of peptone material from untreated serum, but that alkali-denatured serum reaches a limit in concentration above which the double wave changes over to a single wave; (3) that the disappearance of the double wave occurs at considerably lower serum concentrations of infected serum than of normal serum.

Wetting Agents.—Alkaline denaturation at room temperature unquestionably produces more than one change in the structure of a protein molecule. Rupture of secondary linkages, partial hydrolysis of peptide bonds, and a breakdown of disulfides undoubtedly occur. Denaturation by wetting agents, such as Aerosol OT, Duponol PC, Duponol 80, and others³ probably proceeds to a much more limited extent, possibly involving only the liberation of sulfhydryl groups from cystine. Since the polarographic protein wave is supposedly given by -SH-protein as well as by -S-S-protein groups, a preliminary change of the oxidized form to the reduced form by wetting agents should not increase the polarographic wave height, unless a liberation of previously unavailable thiol groups had occurred. If cyclic sulfur compounds of the thiazoline type are part of a protein molecule,⁴ a liberation of new thiol groups by the action of alkali is conceivable and would at least partially account for the increase in polarographic active groups. No information as to the action of wetting agents on these heterocyclics is available. It is, however, unlikely that the wetting agents would liberate thiol groups from thiazolines. When the influence of Aerosol OT on serum was studied, it was found that the polarographic peptone wave, even after twenty-four hours of Aerosol OT contact, was identical with that of the same serum at zero time of Aerosol OT action. This was true for normal serum as well as for the serum of the same dog after a severe pneumococcal infection, although the relative heights of the two sera naturally differed, that from normal serum being the lower.

Enzymes.—The observed differences in the behavior of normal and of infected sera toward alkali, and the consequent belief that an alteration in the chemical structure of the proteins had occurred during infection, prompted us to investigate their enzymatic hydrolysis. It was hoped that pepsin and trypsin would digest normal serum proteins at a rate measurably different from that of infected serum; however, no differences were observed. Consequently, only the digestion polarograms of normal serum are shown in Fig. 5, where curve I represents the peptic digestion and curve II the tryptic one. The first current-voltage curve in each series is that of the blank, obtained by substituting saline for the serum. Its wave height must be subtracted from the serum-digestion polarograms if quantitative comparisons are to be made. Qualitatively, it is

quite evident that the polarographic technique lends itself well to proteolytic studies. Any increase in wave height above that of the zero time is due to proteolysis and is, therefore, a measure of the degree of enzymatic degradation that occurs. Furthermore, it permits an approximate estimation of those protein degradation products which were formed during digestion. These are not precipitable by sulfosalicylic acid but have a larger molecular weight than that of free cystine and cysteine, since these two amino acids in the free state give only a wave in cobaltous ammonium chloride buffer but not in the cobaltic buffer used here. Special attention should be called to the straightening out

Fig. 5.—Polarograms of deproteinized dog sera at various stages of peptic (I) and tryptic (II) digestion at 10° C.

of the double wave during peptic digestion of serum, and of the failure to do so in case of tryptic digestion. A change in the structure of the polarographic protein double wave has so far been associated with denaturation and not with hydrolysis. Peptic activity seems to resemble denaturation in this respect, because the straightening out effect is also obtained by heat denaturation⁵ or ultraviolet light irradiation⁶ of serum albumin. Interestingly enough, ultraviolet irradiation of egg albumen causes a decrease in wave height⁶ instead of the increase observed with serum albumin.

The relatively slower digestion of the serum proteins by trypsin than by pepsin is probably due to differences in the enzyme preparations. Since we were interested only in the relative rates of digestion of normal and of infected serum by the same enzyme preparation, no attempt was made to compare the different enzymes.

DISCUSSION

It is well known that when alkali is added to native proteins, denaturation occurs. This is followed by cleavage of the denatured protein into fragments, the sizes of which decrease as the action of the alkali proceeds. These degrada-

tion products are not very clearly defined, but have been classified as metaproteins, proteoses, peptones, polypeptides, and peptides, according to certain arbitrarily defined characteristics. Those products of a molecular weight smaller than that of metaproteins are not precipitated by sulfosalicylic acid; consequently the magnitudes of the polarographic wave heights, as shown in Figs. 1 and 2, are a measure of the smaller protein molecules only. With these facts in mind an attempt will be made to present a mechanism which will describe the course of the alkaline degradation of normal and of pneumococcus-infected dog sera.

If alkali were added to a serum which contained native proteins only and which was free of all other protein degradation products, the sulfosalicylic acid filtrates of such a serum would give no polarographic waves until the first molecules of proteoses were formed. There is an induction period, the length of which would be determined by the rate at which native proteins become hydrolyzed to the metaprotein state (k_1) and by the average of the rates of degradation of the latter to proteoses (k_2). On the other hand, if the higher proteins coexisted with proteoses and peptones in untreated serum, then the filtrate after the addition of sulfosalicylic acid would give a polarographic wave, the magnitude of which would reflect the concentration of pre-existing peptone molecules. The course of the reaction after the addition of alkali to such a serum would be determined by the relative amounts of pre-existing native proteins, metaproteins, and peptones, as well as by the relative rates of k_1 , k_2 , and k_3 , the latter being the average of the rates of the destruction of the sulfosalicylic acid-soluble protein fractions to particles sufficiently small not to give a polarographic wave in trivalent cobalt buffer. We know that cystine has no influence on the wave in this medium and that glutathione gives a barely visible wave. Preliminary work, which we hope to report soon in detail, has shown that if definite values are assigned to the rate constants in such a manner that $k_1 > k_2 > k_3$, then graphs can be plotted which show the same characteristics in their shapes as the curves given in Figs. 1 and 2, both for normal and for infected sera. In the case of normal serum, which contains relatively small concentrations of peptones, a pronounced induction period would be expected during which no new proteoses enter the sulfosalicylic acid filtrates. However, during this induction period, some of the pre-existing peptones of very low molecular weight are changed to such an extent that they become polarographically inactive, causing a gradual lowering of the wave heights of the polarograms. This period is followed by an interval of peptone accumulation, since the rate of proteose formation from proteins has been postulated as being more rapid than the destruction of peptones, and it is manifested by a rise in the wave height. After all the proteins have been degraded, the polarograms begin to decrease. Experiments carried out, but not included in Figs. 1 and 2, wherein the alkali was allowed to act on the serum proteins for a period of twenty-four hours, have shown that filtrates obtained after sulfosalicylic acid precipitation no longer produce the characteristic polarograms. Further evidence of the correctness of such a reaction mechanism is also borne out by our observation that the nitrogen values of the filtrates decrease during the first fifteen minutes of alkali contact, but then rise again to the original value or above it (Fig. 1, curve III).

The large accumulation of peptone material in the serum of infected dogs prior to the addition of alkali suggests that a degradation of native serum proteins had occurred *in vivo*. Under these circumstances it is reasonable to assume that the sulfosalicylic acid-insoluble fraction does not consist entirely of native proteins, but is a composite of native, denatured, and metaproteins. In such a case no induction period should be expected, as the experimental evidence confirms, and the formation of new proteoses would exceed the rate of peptone destruction, since it was postulated that $k_1 > k_2 > k_3$. Such a mechanism, therefore, accounts for the initial high level in polarographic wave height at zero time, the rapid initial rise after the addition of alkali, and a more sharply defined fall after all of the macroproteins have been converted to sulfosalicylic acid-soluble molecules. The initial fall in the nitrogen values of the peptone fraction of the infected serum, as shown in Fig. 1, curve IV, is the only datum not in complete accord with the reaction mechanism given above. Additional data are being accumulated which, it is hoped, will further clarify this point.

It is thus seen that the observed differences between the action of alkali on normal and on infected sera can be accounted for satisfactorily by the partial *in vivo* destruction of native serum proteins to molecules of lower molecular weight during experimental type I pneumococcus infection in dogs.

SUMMARY

The polarographic protein reaction has been used to study rates of denaturation of serum proteins. No appreciable differences have been found between rates of denaturation of serum from normal and from type I pneumococcus-infected dogs when wetting agents, or pepsin and trypsin are used.

Alkali produces changes in the polarographic rate of denaturation curves, which differ markedly for normal and infected sera. It is suggested that the partial *in vivo* destruction of the serum proteins during infection to molecules of the size of metaproteins, proteoses, and peptones can account satisfactorily for the observed differences.

We gratefully acknowledge the invaluable help and the unstinted cooperation we received in this study from Dr. W. Harry Feinstone of this laboratory. Dr. Feinstone, while actively studying related phases of pneumococcal infection in dogs, kindly took over the culturing of the pneumococci and the actual infection of the dogs, and followed the progress of the disease systematically with x-ray photographs.

LABORATORY METHODS

GENERAL

THE INTRAVENOUS ADMINISTRATION OF OXYGEN*

EDWIN E. ZIEGLER, M.D., BOSTON, MASS.

THE purpose of this paper is to present a new apparatus which is designed for the carefully controlled intravenous administration of oxygen.

The idea was conceived that anoxemia could be relieved by the intravenous administration of oxygen. It was believed that this method of administration could be made available for those cases in which oxygen therapy, by the usual route, was not adequate.

The intravenous administration of oxygen to patients is not new. It has been reported several times. In the past, however, technical difficulties with the apparatus available prevented the use of this method of oxygen administration.

In this preliminary report is described an apparatus which is now being used for the intravenous administration of oxygen. The results are highly satisfactory and further work, including case reports, will be made the subject of later papers.

In 1902 Mariani¹ injected 120 c.c. of oxygen in forty-five minutes into a dying tuberculous patient (rate of 160 c.c. per hour). He reported that the pulse rate and respiration were improved. The treatment was not repeated. The patient died the next day.

Tunnicliffe and Stebbing² in 1916 treated three very ill patients with oxygen intravenously. Their apparatus consisted of a cylinder of "Brinn's oxygen," which contained, they thought, about 1.5 per cent of nitrogen; an "endurance regulator"; pressure tubing; a piece of glass tubing drawn out at the end; a wash bottle and a screw clip on the tubing. The wash bottle contained a solution of 2 per cent sodium carbonate, part of which was blown out by the stream of oxygen and part remained to wash the remaining stream. The amount of oxygen given was estimated by counting the number of bubbles per minute coming through the wash bottle. These authors state that oxygen can be given at the rate of 600 to 1,200 c.c. per hour, that cyanosis and dyspnea are rapidly relieved, and further: "The beneficial results of the intravenous injection of oxygen were certainly more permanent than could apparently be explained by the mere relieving of the cyanosis." The work done with patients fully confirms this observation. Tunnicliffe and Stebbing conclude their paper as follows: "The object of this preliminary note is not to indicate the specific pathological conditions in which the intravenous injection of oxygen should be used, but simply to point out that in those cases in which

*From the United States Marine Hospital, United States Public Health Service.
Received for publication, January 24, 1941.

the inhalation of oxygen either cannot be practiced or gives inadequate relief, the intravenous method of oxygen administration, if carefully carried out in accordance with the directions, is available to the clinician and will give therapeutic results."

Singh and Shah,³ of the Haffkine Institute in Bombay, in 1940 gave oxygen to six patients with severe pulmonary disease. These workers used two different methods. The first consisted of two syringes, moved by screws, working alternately, to pump the oxygen into the vein. There was a pause of five to ten seconds between the actions of the plungers in the syringes. (This allows blood to flow into the end of the needle in the interval when oxygen is not coming through, increasing the danger of clot formation in the needle. Such a clot, if formed, would be dislodged into the venous blood stream when the oxygen flow is resumed.) The second method was similar to that of Tunnicliffe and Stebbing,² which they found was hard to control and was apt to produce pulmonary embolism. With the first method they incorporated a manometer to register the venous pressure, which also indicates any stoppage in the flow of oxygen.

Singh and Shah³ found that the signs and symptoms of pulmonary gas embolism in man are the same as those in animals. They state: "With slight embolism there is a rise in blood pressure and pulse rate; this does not indicate any danger, and the oxygen should not be withheld. With a greater degree of embolism the blood pressure falls, the pulse becomes feeble, and cyanosis increases. The patient complains of a sense of impending dissolution, uneasiness over the chest, shortness of breath and pain over the precordial region. Oxygen embolism, however, unless carried to extreme is not dangerous." The above authors further state, "all these (six) cases showed clinical improvement for 24 to 48 hours after injection, as indicated by raised blood pressure and improved pulse."

Summarizing their report, Singh and Shah³ state: "In man about 10 to 20 c.c. of oxygen a minute (600 to 1,200 c.c. per hour) can be administered intravenously; this is about 10 per cent of the basal requirement. This is the only method by which any considerable quantities of oxygen can be administered by an extrapulmonary route. This amount of oxygen does not appear to be considerable, but still a distinct clinical improvement follows its administration."

The work with animals has been more extensive, but it has, on the whole, not been performed carefully enough and has been very misleading for technical reasons, which will be pointed out.

The first workers to inject oxygen intravenously were Nysten⁴ in 1811 and Demarquay⁵ in 1866. They used dogs.

Gaertner⁶ in 1902 also gave oxygen intravenously to dogs. He stated that it did not obstruct the circulation through the lungs. He found bubbles of gas in the right ventricle but never in the left; he contended dangerous symptoms can immediately be relieved by withholding the oxygen. In 1904 Stuerz⁷ injected oxygen intravenously in dogs. He recommended intermittent injections and minimized the possibility of embolism. These injections constitute one of the technical faults which have, in the past, led to the abandonment of this form

of therapy. Intermittent injections cause (1) clotting in the needle, or (2) frequent withdrawal of the needle, and as frequent subsequent venipunctures.

More recent experimental work with animals has apparently been more carefully performed, especially with reference to the measurement of the amount of oxygen administered in relation to body weight. The recent work, however, incorporates practically the same technical errors present in the older methods.

Bourne and Smith⁸ in 1927 performed experiments with dogs. They state: "It is seen, however, that in amounts (of oxygen) that would provide some hope of the supply of an adequate amount, pulmonary embolism and right heart insufficiency produce an even greater degree of anoxemia than that already in existence." Here lies the cardinal reason for the failure of former investigators to make the intravenous administration of oxygen successful. It has always been *assumed* that it would be necessary to give an amount of oxygen which would approximate the total or basal requirement of the body. This concept we have found to be erroneous. The fact has been overlooked that the body is (even in severe anoxemia) getting *some* oxygen through the lungs.

Bourne and Smith⁸ gave dogs from 0.75 c.c. to 3 c.c. of oxygen per kilogram per minute. This corresponds to a rate of 3,150 c.c. to 12,600 c.c. of oxygen per hour for an average 70 kg. man. In contrast, I have obtained favorable results in man by the intravenous administration of from 200 to 1,000 c.c. per hour, and have given oxygen at these rates for periods up to nine hours continuously.

Macdonald Dick⁹ in 1939, following the lead of the afore-mentioned workers, gave oxygen to dogs in the femoral vein. He administered 2 to 3 c.c. of oxygen per kilogram of body weight per minute "with safety" and stated that "much larger amounts can be given for short periods." Converting these amounts to values for an average 70 kg. man, we find that they amount to 8,400 c.c. to 12,600 c.c. per hour. Again, too much oxygen was given. In fact, the amount given was ten times that which has been found to be therapeutic.

In the past the failure to obtain beneficial results in a *practical* manner has been due to several factors. Former workers were under the influence of a great curiosity as to the effects of embolism. They made it a point to give so much oxygen that they could observe the effects of severe oxygen embolism.

Animal experimentation as performed up to this time has exhibited several other defects. Most workers with animals have neglected or considered it unnecessary to produce oxygen want. They have not used apparatus which could supply a constant flow of oxygen at the low rate of flow required.

When too much oxygen is administered by the intravenous route, the difficulty is not due to embolism in the ordinary sense. It is due to what is called *tampon*, caused by blood froth in the lungs and right heart. This phenomenon is also called *vapor lock*. These difficulties are no longer of any importance when oxygen is administered intravenously at a constant volume and pressure, each of which is carefully controlled. This is possible with the apparatus described below.

THE APPARATUS

Any apparatus used for the intravenous administration of oxygen must meet certain definite requirements. It must be easily regulated. The amount

of oxygen which is delivered must be directly indicated by a manometer scale calibrated in cubic centimeters of oxygen per hour. The volume of oxygen delivered by the apparatus should range between 100 and at least 1,200 c.c. per hour. The flow of oxygen must be continuous and not intermittent. The apparatus must also be so constructed that the flow of oxygen will not be stopped by an increase in the venous pressure. The apparatus consists of the following:

A tank of medicinal grade oxygen, which should be at least 99.5 per cent pure. Such cylinders of oxygen are commercially available. The size of the oxygen tank may be whatever is convenient; a small tank, such as a 20 or 40 gallon tank, would be relatively light, take little space, and could be readily transported.

Attached to the oxygen cylinder by a yoke is a double pressure reducing valve. Attached to the yoke is an indicator showing the pressure of the oxygen in the tank. The first of the pressure reducing valves is a fixed valve requiring no adjustment. This valve reduces the high pressure in the tank to a low level approximating some convenient low pressure, such as 5 pounds per square inch.

The second of the pressure reducing valves through which the oxygen must flow is adjustable. This valve must be so constructed that it will deliver a pressure ranging from zero up to about 200 mm. of mercury, as set. The spring and screw which regulate this valve must be so designed that the pressure can be easily adjusted with an accuracy of 1 to 2 mm. of mercury or better. The outlet from the adjustable pressure reducing valve must have a manometer attached to it to indicate the reduced oxygen pressure. This manometer can be of the mercury type or the so-called aneroid or spring type. Whichever type of manometer is used, it should be calibrated in millimeters of mercury from zero to at least 200 mm., it must also be calibrated to show the flow of oxygen in cubic centimeters per hour.

From the outlet of the second pressure reducing valve the oxygen is conducted by tubing to a filter which contains a convenient number of layers of cotton and calcium chloride or anhydrous calcium sulfate, or some other efficient dehydrating substance. The purpose of this filter is to make sure that the oxygen will be dry. From the filter the oxygen is conducted through more tubing to a small chamber containing a resistor.

This resistor may consist of a porcelain block or a block of some other suitable porous substance, such as porous bronze. The pressure of the oxygen will force it through this porous block. The rate of flow of the oxygen will be directly proportional to the difference in pressure between the oxygen on the proximal side of the porous resistance block and the pressure of the oxygen on the distal side of the porous resistance block, multiplied by a factor which will be constant for any given resistance. This latter factor would have to be determined by the calibration of each apparatus constructed.

Incidentally, the dehydrating filter and the porous fixed resistor would each remove any foreign particulate matter from the oxygen flowing through the apparatus if any was present.

From the housing containing the porous resistor, the oxygen is conducted by tubing to two places. First, the oxygen is conducted back to the mercury or aneroid manometer, but to the opposite side of the manometer, so that the manometer shows directly the difference between the pressures on each side of the fixed resistance. Second, it is conducted through tubing to a wash bottle where the oxygen bubbles through a liquid such as distilled water. This makes the flow of oxygen visible and humidifies it.

From the wash bottle the oxygen is conducted through a suitable outlet to which is attached in each case, before the apparatus is used, a sterile outfit consisting of a sufficient length of rubber tubing, a small two-way valve so that a syringe may be attached to the tubing, a glass adapter, and a needle for injecting the vein. I have adopted a 22 gauge needle.

To use the apparatus the oxygen is turned on and allowed to flow for a reasonable time so as to wash out any residual air. While the oxygen is flowing, the needle is inserted into the patient's vein.

When a tourniquet is used to distend the veins, it causes an appreciable increase in venous pressure. Therefore, when the needle is first injected, and before the tourniquet is released, a small amount of blood may flow into the needle. However, when the tourniquet is released, the oxygen pressure immediately pushes the blood back into the blood stream. There is a small amount of blood remaining which adheres to the surface of the lumen of the needle. This blood may be washed out of the needle by attaching a syringe containing a solution of sterile sodium citrate or other suitable anticoagulant solution of suitable strength to the small two-way valve. The valve is so adjusted that the citrate solution can be injected from the syringe into the rubber tubing just proximal to the glass adapter. The valve is then adjusted to cut off the flow from the syringe and to allow the oxygen to flow through the sterile rubber tubing. The oxygen coming through pushes the sterile citrate solution through the glass adapter and the needle, washing out any blood which may be present. This process of adding citrate solution to the tubing can be used previous to the initial injection of the needle into the vein.

It is also recommended that the apparatus have a manometer, preferably of the aneroid type, with a range from zero to about 60 mm. of mercury. This manometer is attached by tubing to the apparatus at some point between the fixed resistance block and the sterile rubber tubing. It is suggested that it be attached so as to show the pressure of the oxygen in the wash bottle. This pressure will correspond very closely to venous pressure.

Normal venous pressure ranges between 4.4 and 8.8 mm. of mercury. In heart failure venous pressure will rise from about 9 mm. of mercury to as high as 30 mm. of mercury in severe grades. If there is any stoppage in the apparatus, such as would occur if a clot were to form in the intravenous needle, this would be indicated by an unusual rise in pressure, as shown by the gauge. This gauge also provides valuable clinical information as to the degree of heart failure.

The outlet in the wash bottle from which the oxygen bubbles must have a small aperture. If this aperture is large, the bubbles coming through will be large and will cause a "bump effect," which is really a slight variation in the

pressure of oxygen. This effect may cause an uneven flow of oxygen into the vein. The apparatus must be so constructed that the oxygen flow is always uniform.

One should use a new stainless steel needle, entirely free of corrosion, or a gold or platinum needle. See Figs. 1 and 2 for further details.

Fig. 1.—Apparatus for intravenous oxygen therapy. Schematic drawing: *a*, tank of compressed oxygen; *b*, screw for fastening yoke to tank; *c*, yoke; *d*, valve for opening tank; *e*, tubing; *f*, gauge showing tank pressure; *g*, fixed pressure reducing valve; *h*, adjustable low pressure reducing valve; *i*, screw for adjusting oxygen pressure and volume of flow; *j*, manometer showing volume of oxygen flow; *k*, fixed porous resistance; *l*, wash bottle; *m*, venous pressure gauge; *n*, *o*, *p*, *q*, sterile tubing, two-way valve, and adapter for receiving glass syringe, glass adapter, and intravenous needle.

The apparatus I have devised always operates under positive pressures of oxygen without interruption or variation, except as adjusted. Any leak developing in this apparatus could not possibly admit air, as oxygen would escape from the apparatus to the outside, preventing air from gaining access to the apparatus.

An additional advantage of this apparatus is that it always supplies oxygen by pressure which is slightly greater than that of the venous pressure. If the venous pressure varies, the pressure in the apparatus will vary accordingly, always remaining slightly higher than the venous pressure. Other types of apparatus that have been used experimentally and that have not been practical for therapeutic work have supplied oxygen at pressures determined by the characteristics of the apparatus without respect to the venous pressure.

Another advantage of the apparatus is that it requires no pump device or electric motor. The oxygen proceeds through the apparatus by virtue of the pressure of the oxygen in the compressed oxygen cylinder. Thus the apparatus can be used at any place, whether or not there is a source of energy, such as electric power.

CLINICAL CONSIDERATIONS

Cases will be reported in detail later. A large variety of disease conditions in which oxygen therapy is indicated has not been available up to this time. However, the patients who have been treated have shown in general the following results: Cyanosis is abolished. The pulse rate becomes lower.

The blood pressure, if low, tends to rise. The mental state becomes clearer. One patient who was comatose became conscious within a few minutes. One who had severe pulmonary edema was entirely relieved of the edema after twelve hours, following a five-hour intravenous administration of oxygen.

Various comments have been made voluntarily by patients to the effect that they preferred this form of oxygen therapy to others which they have experienced.

Fig. 2.

The treatment is no more complicated than the administration of solutions intravenously, and the apparatus requires but little more attention. The nursing care of the patient is much easier than when he is in an oxygen tent. No unfavorable reactions, subjective or objective, have been observed thus far.

I have not had the opportunity to study the signs and symptoms of pulmonary oxygen embolism, which others have observed, because I do not give enough oxygen to cause pulmonary embolism. According to Singh and Shah,³ the signs and symptoms of pulmonary gas embolism (tamponade) are the same as those observed in animals. These authors state, "With slight embolism there is a rise in blood pressure and pulse rate; this does not indicate any

danger; and the oxygen should not be withheld." With this statement I cannot entirely agree. I believe that if an amount of oxygen is being given, which causes a rise in blood pressure with a corresponding rise in pulse rate, the flow of oxygen should be reduced in amount. The signs and symptoms of pulmonary oxygen embolism apparently furnish adequate warning of an overdose.

In my experience, using therapeutic amounts of oxygen, averaging 200 to 600 c.c. per hour, I have observed that when the blood pressure is low, as in shock or heart failure, it will rise. There is also an accompanying slowing of the pulse rate and a less labored and a slower respiration. *Thus the pulse rate and the respiratory rate are the important things to observe during the intravenous administration of oxygen.* An appreciable increase in pulse rate and respiratory rate occurring during the administration of oxygen would indicate that the rate of oxygen administration was too great.

ECONOMICS

On a twenty-four-hour basis the cost of the oxygen administered intravenously would not be over ten cents, and would probably be somewhat less. Contrasted to this, the cost of oxygen, on a twenty-four-hour basis, as administered by tent might range anywhere from \$6.00 to \$20.00. The original cost of the apparatus would be much less than the average type of apparatus used at the present time for administering oxygen by other routes.

DISCUSSION

It is my belief that the intravenous administration of oxygen is more effective and very much less expensive than other methods of oxygen therapy.

The improvement observed in patients seems to be all out of proportion to the small amount of oxygen administered. This is rather difficult to explain in exact scientific terms. But an explanation is offered as follows:

When oxygen is administered intravenously, the body is getting something that it urgently needs without expending any energy. It requires a certain amount of energy for the pumping action of the heart and the respiratory movements of the chest to obtain oxygen for the use of the tissues. Any oxygen given intravenously reduces the amount of work thus required of the heart and chest. In addition to this, the physiologic processes of the body, in general, seem to be improved, no doubt as a result of improved tissue metabolism.

When oxygen is given intravenously, it provides opportunity for reduced hemoglobin to absorb oxygen directly. This direct absorption of oxygen by hemoglobin can occur in the vein, in the right side of the heart, and finally in the vessels of the lungs. That this absorption does occur is shown by the clinical improvement which results.

If one listens with a stethoscope over the tricuspid area of the chest during the intravenous administration of oxygen, one hears bubbles of oxygen rushing about in the right side of the heart. If one then listens over the mitral area of the chest, no bubbles can be heard. This is an indication that the oxygen is absorbed before it reaches the left side of the heart.

Another possibility remains; this is, that the oxygen, or a portion of it, may not all be absorbed by the venous blood and may pass from the lung capillaries into the alveoli of the lung. On the grounds of clinical evidence I do not believe that this happens. Dick⁹ studied this point and states, "it should be noted in this connection that the oxygen consumption of the animal remained unaltered, the oxygen introduced by vein being compensated for by a decreased absorption from the lung." This finding, based on careful work done by Dick, was in spite of the fact that he gave approximately ten times as much oxygen as I have found necessary for therapeutic results.

The clinical evidence of improvement is perhaps not sufficient to convince all of the value of this method of treatment. It is proposed to measure the oxygen consumption with a metabolism apparatus before and during the intravenous administration of oxygen in a manner similar to that used in animal work by Dick.⁹ Another laboratory method which I expect to use is the analysis of arterial blood for its oxygen content before and during the intravenous administration of oxygen.

It is believed that the effect of the intravenous administration of oxygen should be determined in certain types of mental disease, such as alcoholism and dementia praecox.

Another brief discussion of oxygen embolism is in order. The phenomena of air embolism are produced by nitrogen. Bubbles of nitrogen present in the capillaries of a tissue will shut off this tissue from its supply of oxygen. In contrast to this, bubbles of oxygen in the capillaries of a tissue cannot shut off this tissue from its supply of oxygen. Animal and human experiments indicate that tissues will gradually absorb these bubbles of oxygen. When this happens, the blood flow through the capillaries is again re-established, and the tissues in the meantime have not been deprived of oxygen.

I have been informed that medicinal grade oxygen is 99.5 to 99.8 per cent pure. The impurities present are said to consist mostly of nitrogen with slight traces of other inert gases. From what I know of the elimination of nitrogen in caisson disease, it can be assumed that this amount of nitrogen is of no significance. In general, those who have employed oxygen intravenously in the past have not had available a supply which was 99.5 per cent pure.

Two contraindications to the intravenous administration of oxygen have been discovered. When there is a marked diminution in the capacity of the vascular bed of the lungs, such as occurs in advanced tuberculosis and emphysema, the amount of oxygen given intravenously should be greatly reduced in amount, or not given at all.

When there is a marked dilatation of the right ventricle, as shown by an unusually high venous pressure, intravenous oxygen may be of no avail. The above conditions are obviously related, since increased resistance to the flow of blood through the lungs is the usual cause of dilatation of the right ventricle.

The apparatus presented may be used experimentally for the intravenous administration of gases other than oxygen, such as gaseous anesthetics, gas-oxygen mixtures, and other gases.

SUMMARY

An apparatus has been devised and described which makes the intravenous administration of oxygen safe.

The intravenous administration of oxygen to patients has, in my experience thus far, been more effective than oxygen administered by any other routes.

The cost of the administration of oxygen intravenously is almost insignificant in comparison with administration by other methods.

It is believed that the intravenous administration of oxygen can be used in most of the conditions in which oxygen therapy is indicated.

CULTIVATION OF *SPIROCHAETA PALLIDA* ON THE CHORIO-ALLANTOIC MEMBRANE OF THE DEVELOPING HEN EGG*

J. LAMAR CALLAWAY, M.D., AND JANE SHARP, A.B., DURHAM, N. C.

MANY attempts have been made to cultivate *Spirochaeta pallida* on artificial media.¹⁻⁷ At present, however, infected rabbits are the only reliable source of the organisms for experimental purposes. To obtain fairly large quantities of spirochetes more conveniently, and possibly more quickly, we have attempted their cultivation on the chorio-allantoic membrane of the developing egg. Sterzi and Staudacher⁸ have reported survival of the organisms on the chorio-allantois of the egg for six hours, and retention of virulence for two hours, using the Truffi strain of *S. pallida*.

In our work the Nichols strain† was used directly after one rabbit passage. The material used in the beginning was a frozen 50 per cent testicular mince suspended in 1 per cent neopeptone veal infusion broth, pH 6.9.⁹ The mince was thawed rapidly in a 37° C. water bath, and 0.25 c.c. was injected into the right testicle of a healthy male rabbit. The animal showed characteristic lesions of rabbit syphilis thirty-nine days after inoculation. A dark field of the testicular fluid revealed many motile spirochetes. The rabbit was sacrificed by injecting 20 c.c. of air into the external vein of the left ear. The testicle

Received for publication, October 21, 1940.

†This material was kindly furnished by Dr. W. L. Fleming, of the Division of Public Health, University of North Carolina.

was excised, cut into pieces of about 5 c.mm., and ground for ten minutes with sterile sand. One per cent Difco peptone beef infusion broth, pH 7.4, was used to make a 50 per cent suspension by weight of the testicular material. The suspension was well mixed, and the sand and heavy tissue were thrown down by centrifuging at low speed (350 r.p.m.) for five minutes.

Fig. 1.—Rabbit No. 15, fifty-nine days after inoculation.

Using the Goodpasture technique,¹⁰ 0.1 c.c. of the supernatant fluid was dropped onto the chorio-allantoic membrane of each of ten fertile hen eggs which had been incubated ten days at 38° C. After inoculation the eggs were returned to the 38° C. incubator. The time elapsed from the rabbit's death to inoculation of the eggs was one and one-half hours.

One of the embryos ceased normal movement seven hours after inoculation. At this time, 0.25 c.c. of its chorio-allantoic fluid was injected into each testicle of a healthy male rabbit (No. 14). The material injected showed a few feebly motile spirochetes by dark-field examination. However, no syphilitic lesions have been observed in the rabbit in ninety days.

A second embryo was dead twenty-seven hours after inoculation. This egg was opened, and 0.25 c.c. of its chorio-allantoic fluid was injected into each testicle of another healthy male rabbit (No. 15). Dark-field examination showed one or two sluggishly motile spirochetes per field. Forty-seven days after inoculation the right testicle of this animal was swollen and indurated, the left testicle remaining normal in appearance. Fifty-nine days after inoculation both testicles were greatly swollen and hard masses could be felt. There was a chancre-like lesion 2 cm. in diameter on the left testicle (Fig. 1), and numerous motile spirochetes could be seen in dark-field preparations.

On the sixty-fourth day following inoculation, rabbit No. 15 was sacrificed; both testicles were cut and ground with sterile sand, then mixed with Difco peptone beef infusion broth, pH 7.4, to make a 50 per cent emulsion by weight. The supernatant liquid was prepared by centrifuging as before, and 0.5 c.c. of it was used to inoculate another rabbit (No. 19). At this time, the preparation showed many motile spirochetes by dark-field examination. The remainder was frozen and preserved at -78°C .

Tissue sections of the liver and heart of the embryo from the egg used to inoculate rabbit No. 15, stained by Levaditi's method, showed no spirochetes. The remaining eight of the ten eggs inoculated were allowed to hatch, and the chicks appeared normal for ten days, the limit of observation. Tissue sections of their hearts and livers taken at this time showed no recognizable spirochetes.

Twenty-four days after inoculation rabbit No. 19 showed swelling and induration of both testicles. Thirty days after inoculation dark-field preparations of material aspirated from each testicle showed numerous motile spirochetes.

The infection of rabbit No. 15 indicated that virulent spirochetes of the Nichols strain will live twenty-seven hours in the developing hen egg and, in some cases, will retain their virulence for that length of time. The infection is transferable from one rabbit to another, the first rabbit-to-rabbit transfer producing rabbit syphilis within the normal time limit. More work is necessary to determine how great a percentage of the egg inocula will live, whether spirochetes will multiply in the developing egg, and in which part of the egg surviving or growing spirochetes are most abundant.

TENSILE STRENGTH OF HAIR AND HAIR ROOTS

MAN HING AU AND EMIL BOGEN
OLIVE VIEW, CALIF.

IN THE preparation of animals for intradermal or subcutaneous injections, the usual practice is to shave the dry or lathered hair with a razor, sometimes after preliminary clipping with a scissors or hand or electric clipper.¹ Occasionally a chemical depilatory, such as barium sulfide, is used. At the Olive View Sanatorium it has been found simpler to pull out the hair from the guinea pigs in about half a dozen tufts, thus clearing a space large enough for the injection. This plucking is faster, lasts longer, and produces less local irritation. Only a few seconds are required, as compared with the longer time needed for clipping, lathering, shaving, and getting, cleaning, and replacing the clippers and razors, or applying and removing the depilatory. The part which is plucked remains bare for many days longer than the part which is shaved, thus allowing better observation of local reactions that may occur. With the plucking of hair, the guinea pig skin is left smooth and pale, and no inflammatory reaction follows, so that the reaction to injections may be readily noted. On the other hand, shaving is not only followed by gross cuts and injuries, but microscopic examination of the freshly shaven skin indicates that many subvisible lesions may also be inflicted, any of which increases the chances for local irritation, inflammation, and infection.

Insofar as sensation or distress can be gauged by the behavior of the animals, it appears that plucking is less painful to the guinea pigs than the more prolonged procedures of shaving or applications of epilating pastes. The guinea pig hair usually comes out so readily that there is not the tension on the skin, which is the usual cause for pain in hair-pulling. Guinea pigs seem much more frightened than hurt by the procedures in general, and soon become used to handling. They usually utter the greatest amount of audible complaints, squeals, etc., while they are being sought and picked up, subsiding soon after they are firmly grasped. If not too great a tuft of hair is taken at each time, and the plucking is done rather brusquely, they may make no further protest during the entire procedure, or at most only a single yelp at the first touch. With a little practice technicians become so adept at this mode of epilation that they can prepare a large number of animals for testing within a few minutes, with practically no complaint on the part of the subjects.

The ease with which hair may be plucked from guinea pigs is markedly in contrast with the resistance to such hair-pulling shown by rabbits and other animals, especially the fur-bearing species. For such subjects, shaving offers a much better means of baring the skin. Very simple observations were suf-

ficient to demonstrate that this was the case. Even the removal of a few hairs from a rabbit is difficult; to pluck a large clump of hair may result, if sufficient force is used, in actual disruption of the skin, if the hair does not, as is more often the case, break in the grasp.

In order to obtain quantitative data regarding the ease of removal of hair from the guinea pig, a series of simple measurements was undertaken. A light wire spring scale was calibrated by attaching various small weights, from 1 to 100 Gm., to a mosquito forceps at its lower end. When the forceps grasped a hair instead, and the spring scale was withdrawn, the elongation of the spring and the corresponding tension exerted were readily observed.

Ordinary human hair, pulled from the forearm of an adult male, exerted a tension of from 5 to 25 Gm. before extraction, with an average of 12 Gm. per hair. Thereafter, pulling at the extracted hair until it broke off somewhere in its length required another force of from 8 to 32 Gm., with an average of 18 Gm. per hair.

Accordingly, a human hair will usually, when pulled sufficiently, come out from the skin, but if jerked rapidly, it is apt to break off, since the breaking stress is about 50 per cent greater than that of epilation.

On the other hand, hair from the back of a guinea pig came out with the application of from 1 to 5 Gm. force, usually about 2 Gm. However, the same hair could not then be broken without the application of from 10 to 52 Gm. of tension, averaging about 25 Gm. It appears, then, that the hair of the guinea pig is really somewhat stronger than that of man, but that the hair root in the guinea pig is quite fragile, releasing the hair at less than one-sixth the tension required to pull out a human hair, and less than one-twelfth the force required to break off the hair. Accordingly, the chances of breaking off the hair on plucking a guinea pig, instead of extracting it, are very slight.

Further studies in the same manner may be desirable to elucidate the effect of season, sex, age, pregnancy, hair, and skin color, hair length and thickness, curliness of hair, etc., as well as the effects of various diets, diseases, and environmental factors on the hair of different species.²

The present study merely documents the previously observed fact that the hair of the common guinea pig is readily removed by simply plucking it out in clumps, and that this makes a much simpler and more effective way of epilating a guinea pig than does shaving, clipping, or the application of depilatory paste or lotions.

AN INEXPENSIVE ANIMAL COMPRESSION CHAMBER*

EDGAR END, B.S., M.D., MILWAUKEE, WIS.

IT IS possible to construct a simple and efficient compression chamber for small animals at very low cost. The chamber described here was built in the school shop at a cost of less than \$15.00 and has given almost uninterrupted service for four years. It was originally used in animal experiments incidental to the development of helium-oxygen mixtures for use by divers and others working under increased atmospheric pressure.¹ It can be used to subject rats, mice, guinea pigs, and small rabbits to increased pressure in any gas or mixture of gases. By substituting an appropriate gauge and using suction instead of high pressure, it may be employed in experiments in reduced pressures as well.

The body of the chamber consists of a 1-foot section of 6 inch standard steel pipe, carefully squared on the ends. Next, a circular steel plate 10 inches in diameter and $\frac{5}{8}$ inch in thickness is converted into the door or back cover of the chamber. This plate is centered in a lathe, and a shallow, circular trough is cut into one face. The trough is just wide enough to accommodate the end of the 6 inch pipe comfortably. Later this trough is filled with melted lead to form a gasket. The center is then cut out of a second plate of the same size. The ring thus produced is just large enough to slide over the outside of the chamber and form a collar for it. This collar is later welded in place 1 inch from the back end of the chamber. A third plate of the same size has a 4 inch circle cut from its center, with the cut beveled $\frac{3}{4}$ inch toward the outside. This last plate covers the window of the chamber and holds it tightly in place. The window itself consists of a $6\frac{3}{4}$ inch circle of plate glass 1 inch in thickness.

The various parts of the compression chamber are held together by eight steel rods made from eight 16 inch lengths of $\frac{3}{4}$ inch mild steel rod, threaded for a distance of $1\frac{1}{2}$ inches on one end and for $3\frac{1}{2}$ inches on the other. These rods pass through holes drilled in the collar and end plates of the chamber. First the two end plates are drilled with eight $\frac{13}{16}$ inch holes spaced evenly around the margin, with their centers $\frac{7}{8}$ inch from the edge. Using these plates as a template, the collar is then drilled with eight holes which are tapped to take the threaded rods. The rods are all threaded through the collar from one side, using the ends which had been threaded for a distance of $3\frac{1}{2}$ inches. The collar is then easily held in position while being welded to the chamber by placing the two end plates in position over the ends of the rods and drawing them up snugly by means of nuts.

*From the Department of Physiology, Marquette University School of Medicine, Milwaukee.

Received for publication, January 28, 1941.

Fig. 1.—Compression chamber showing view through window; method of attaching gauge and valve; and back cover removed to show lead gasket.

Fig. 2.—Back view of chamber with cover in place. The tray for chemicals and the screen floor of the chamber are shown.

The chamber is assembled by placing a thin, paint-soaked leather gasket between the end of the pipe and the window, and a plain gasket between the window and the plate which covers it. This plate is then drawn up very tightly and evenly by means of nuts on the ends of the $\frac{3}{4}$ inch rods. The cover of the chamber is tightened in place in the same way. The cover and one of the rods are punch marked to insure replacing the cover in the same position every time. After the nuts have been tightened and released several times, the lead gasket becomes shaped to the end of the pipe and forms a tight joint when the cover is drawn up tightly and evenly.

The chamber is completed by drilling a hole through the top and threading into it a short piece of heavy $\frac{1}{2}$ inch brass pipe, to which is attached a brass cross. A pressure gauge is then attached to the vertical arm of the cross, and a needle valve to each side arm. Such an arrangement permits the introduction of gas through one side arm and its subsequent removal through the other one. Also, two gases or mixtures of gases can be used by introducing one from each side. As can be seen from Figs. 1 and 2, a packing box has recently been substituted for one of the needle valves to permit an insulated wire to be run into the chamber to provide current for illumination whenever it is desired to photograph the animals.

Carbon dioxide and moisture may be eliminated by ventilating the chamber; a galvanized iron tray of chemicals beneath the screen floor assists in this elimination. The bottom of this tray is filled with calcium chloride to absorb moisture. A blotter saturated with concentrated sodium hydroxide solution, to absorb excess carbon dioxide, is supported on a screen above the tray. The floor of the chamber is made of heavy screen placed high enough above the blotter to prevent any caustic from coming in contact with the animals.

The chamber before being used for experiments should be tested by filling it with water and then subjecting it to a pressure considerably higher than any that will be used experimentally. A cylinder of compressed air provides a very convenient source of high pressure for this test. Leaks will be betrayed by the escape of water, and no violent explosion will occur if any part breaks. It is theoretically safe to employ pressures of several hundred pounds per square inch in this chamber, but we have never had occasion to use pressures in excess of 100 pounds. If high pressures are used, a mirror should be arranged to permit the observer to see the inside of the chamber without standing in front of the glass window itself.

SUMMARY

The construction of an experimental compression chamber at a cost of less than \$15.00 is described. In this chamber rats, mice, guinea pigs, and small rabbits can be subjected to pressures in excess of 100 pounds per square inch in any gas or mixture of gases, and their reactions can be observed. The chamber may be employed in studying the effects of reduced pressure.

A DIRECT PLETHYSMOGRAPHIC METHOD FOR DETERMINING THE BLOOD PRESSURE IN THE UNANESTHETIZED RAT*

SYDNEY M. FRIEDMAN, M.D., M.Sc., MONTREAL, CANADA

WITH the development of techniques for producing hypertension in the rat, many investigators have attempted to devise methods for the indirect measurement of blood pressure in small rodents. Early methods made use of anesthetized animals,¹ but since the anesthetic itself had some effect on the blood pressure, methods were sought for use on the nonanesthetized animal. The first of these was that of Diaz and Levy,² which gave reliable results but necessitated the cutting of the tail and some loss of blood. Williams, Harrison, and Grollman designed an ingenious apparatus which, in their hands, gave very consistent results.³ In the course of our investigations this method was used with some success, but we encountered several difficulties. In the first place, the method requires that the animals be warmed and trained, and is not always feasible. Furthermore, there is no objective criterion by which to determine whether the animals have been equally warmed. In addition, we found that since the tail is separated from the water in the water chamber by a surrounding thin rubber tube, the apparatus is not very sensitive to small variations in pressure, and works best with a rat whose tail fits close to the rubber tube. In the case of small rats it is not always possible to collapse the tube about the tail without leaving air spaces, and as a result the expansion of the tail at systolic pressure may be taken up by the slack of the rubber tube.

To obviate these difficulties we designed the following apparatus which employs direct plethysmography, and requires neither training nor preliminary heating. In our hands this apparatus has given very consistent results.

DESCRIPTION OF THE APPARATUS (Fig. 1.)

Part 1 consists of a cylinder 2 inches in diameter and 6 inches long, made of continuously perforated tin or other metal. This is closed off at *a* by a cork which can be used to adjust the tube length. The other end is closed by a sleeve cylinder of metal made to fit over the tube (about $2\frac{1}{8}$ inches in diameter). This sleeve is completely closed at *b* except for a $\frac{3}{8}$ inch hole drilled in the center to permit passage of the tail. This part holds the animal.

Part 2 consists of a glass cylinder of 1 inch diameter and $\frac{1}{2}$ inch long, closed at both ends except for the flanged apertures at *c* and *d* as shown. These are $\frac{3}{8}$ inch and $\frac{7}{16}$ inch, respectively. At *e* there is a short glass tube of $\frac{1}{16}$ inch bore to admit air. Cigarette drainage tubing of $\frac{3}{8}$ inch diameter is passed through the two apertures, stretched and cemented over the flanges, and tied down. This completes the pressure cuff. For small rats of less than 100 Gm. a similar cuff is used, but with apertures of $\frac{1}{4}$ inch and $\frac{3}{16}$ inch, respectively.

*From the Department of Anatomy, McGill University, Montreal.
Received for publication, February 17, 1941.

Part 3 is a cylinder of glass, $\frac{3}{4}$ inch in diameter, with a flanged opening of $\frac{1}{4}$ inch at *f*, and closed at *g*. The tube length is 6 inches. At the superior surface of the distal end an S-shaped capillary manometer (0.5 mm.) is placed, which rises 2 inches above the tube. At *h* and *i* stopcocks are placed for water inlet and outlet. A one inch length of $\frac{1}{4}$ inch cigarette drainage tubing is cemented in place over the flange, which when snugly applied to the tail acts as a stopper for that end of the tube. This diameter of tubing is most satisfactory for overall use, while $\frac{5}{16}$ inch will be found better for larger animals (above 150 Gm.) and $\frac{3}{16}$ inch for small animals (less than 100 Gm.). The design of the apparatus permits replacing or changing of the rubber tubing in a few minutes.

Fig. 1.

Fig. 2.

The general arrangement is shown in Fig. 2. The three parts are held together with clamps that slide on a rod. The pressure cuff is connected both to a mercury manometer and to a bulb with a shut-off valve, via a glass two-way connection. The water chamber is connected to a 50 c.c. syringe which acts as a water reservoir and allows the same water to be used without continually replenishing a simple water reservoir. The entire apparatus may be conveniently housed in a three-sided box.

The rat is gently placed in the holder that is then closed with the covering sleeve, allowing the entire length of the tail to protrude freely. The holder is placed in the clamp and the animal is allowed to sit for a minute to accustom itself to the holder. If the animal is very restless, an electric light placed beside the holder will usually give it a little warmth and quiet it. The tail

is then passed through the pressure cuff which is moved, together with its clamp, as close to the holder as possible. Soft vaseline is smeared on the distal end of the tail for about one inch from the cuff, and the tail passed through the sleeve into the water chamber. This latter is moved as close to the cuff as possible, so that a maximum of tail will be immersed in water. However, care must be taken that although the rubber sleeve is tight enough to prevent water leaking out around the tail, it is not tight enough to occlude the blood supply to the distal part of the tail. Such an adjustment is in practice quite simple.

Pressure is applied to the tail to a level of 30 to 50 mm. Hg above the expected systolic level. Water is run in from the syringe via the stopcock, filling the water chamber completely, and rising until the manometer is about half filled. Adjustment of the level in the manometer is most easily carried out by withdrawing water through the outlet stopcock. Pressure is then gradually released.

At systolic blood pressure blood will flow into the tail, and—being unable to return through the still occluded venous channels—will cause the tail to expand and the water to rise in the manometer. This expansion will be represented in the manometer by a rise of 2 cm. to 12 cm. or more. With practice it is possible to distinguish accurately two rates of expansion. The first occurs just at systolic pressure and is very slow so that the water level rises in small jerks. The second occurs 15 to 20 mm. below this and is rapid and fairly smooth. The first readings the beginner will make is this lower one, since it is more obvious, but with a little care the higher first point will be distinguished. It is our impression that the lower point corresponds to the unobstructed inflow of blood at diastolic, and hence that our two points probably correspond to those described by Diaz and Levy.

The following difficulties may be encountered. The animal, although not necessarily excited, may move its tail about. Such tail movements are readily distinguished from the true expansion by their jerky character, the large rise of water in the manometer, and the quick fall back again. If a tail movement occurs at an inappropriate moment, pressure is merely released and re-applied a second time. This may be repeated until one is certain of the reading. Another point of caution is that the water chamber should not contain any air, although one or two small bubbles will not interfere with the recording.

The method requires some practice but will, with care, give reliable and consistent results, both for single or repeated pressures, and requires very little time.

TABLE I

ANIMAL NO.	1	2	3	4	5	6	7	8	9	10	11	12
Body weight	108	129	112	130	116	110	129	109	118	112	128	102
Systolic B.P.	104	108	108	108	106	110	110	108	110	108	104	104

We record in Table I the systolic pressure obtained on 12 normal rats with an average body weight of 124 Gm. The consistency of the pressure levels in these animals is striking and agrees well with the results obtained by direct manometry.⁴

In Graph I we record as an example the continuous systolic and diastolic blood pressures of a rat given a small dose of nembutal (sodium pentobarbital) for other purposes.

The normal pressure of the animal was first obtained, the injection was given, and within five minutes the animal was back in the holder and remained there until completely recovered. We wish to draw attention to the fact that more than half the points on the graph were plotted without the animal being under anesthesia, and to observe that diastolic readings represent the second point discussed in the foregoing description.

Graph 1.

SUMMARY AND CONCLUSIONS

1. A method for the determination of both systolic and diastolic pressures in the nonanesthetized rat is described.
2. Sample records are given to show the magnitude of the results obtained.

AN AUTOMATIC QUADRUPLÉ PIPETTING MACHINE FOR THE RAPID AND ACCURATE DELIVERY OF MEASURED SMALL AMOUNTS OF FLUID*

R. J. LEBOWICH, M.D., H. D. GURSKY, C. F. ACKERBAUER, AND F. A. OPPE
GLOVERSVILLE, N. Y.

A NUMBER of automatic pipettes have been constructed for the delivery of accurately measured quantities of fluids in such tests as the complement fixation test for syphilis. The assemblies of Lorenz¹ and Laird² share the common and significant disadvantage of variation, and therefore, inaccuracy in delivery of fluids due to actuation of the two-way valve by the flow of fluid through it. The automatic pipette of Hartman,³ incorporating a mechanically operated two-way valve, is sound in principle and accurate in operation, but the design of its construction does not readily lend itself to adaptation in a test like the New York State quantitative complement fixation test⁴ for syphilis.

The desirability of an apparatus to dispense accurately and rapidly various fluid reagents in amounts ranging from 0.05 c.c. to 0.2 c.c. in the New York State quantitative complement fixation test for syphilis led to the development of an automatic quadruple pipetting machine of high accuracy and precision. Simple in construction and operation, it demands little or no manipulative skill. Apart from this test, the instrument is of value in any routine method, chemical or serologic in character, requiring the repeated delivery of measured small amounts of different fluids. The prime advantages of its design and construction lie in the elimination of complex gearing, belting, and rheostats, thereby avoiding the frequent breakdowns and changes in speed of delivery accompanying their use.

The instrument (Fig. 1) is driven by a $\frac{1}{20}$ H. P., A. C., 110 volt-60 cycle General Electric small synchronous motor, rotating at an absolutely constant speed of 75 r.p.m. From actual experience it has been determined that the optimum working speed for the average technician is 70 to 90 r.p.m., corresponding to an identical number of deliveries of fluid reagent. Hence, adjustment of the speed of the motor is not necessary. The synchronous motor provides a constant speed and eliminates all electrical regulating devices.

DESCRIPTION OF APPARATUS (Fig. 1)

An adjustable eccentric (*a*) fastened securely and directly to the shaft of the motor converts the rotary motion into a reciprocating one through a Scotch yoke (*b*), held rigidly by side gibs (*c*) which can be adjusted for take-up due to their wear.

*From the Eugene Littauer Memorial and Fulton County Laboratory, Nathan Littauer Hospital, Gloversville.

Received for publication, February 21, 1941.

This eccentric (*a*) moves the pistons (*d*) of the syringes (*e*) in an upward stroke, and at the same time compresses the springs (*f*) which are placed in such a position that the pistons are held firmly against the reciprocating bar (*g*).

Noncorrosive heads (*h*), enclosing double-check valves of a ball-seating fully automatic gravity type, are connected directly to the Luer-Lok syringes. It has been found that this is the most simple and efficient design for the purpose of preventing the passage of fluid in either direction until demanded by the reciprocating stroke of the plunger. The valve is a simple and time-proved device, consisting of a ball seat and a truly spherical ball. The ball seat is angular. The weight of the ball sits in its angularity with a very narrow rim surface, thereby eliminating almost completely any danger of accumulation of foreign matter in the flowing fluids which would interfere with the function of the valve. The two-way valve is actuated by the mechanical action of the syringe plunger upon it with almost complete independence of the flow of the fluid reagents.

Fig. 1.

To the noncorrosive heads are attached inert rubber tubes of 2 mm. thickness in order to eliminate any pulsations leading to collapse of their walls. These, if present, represent a significant source of error in delivery.

Glass nozzles, prepared from carefully selected 1.0 c.c. standard Ostwald pipettes, are inserted into the outlet rubber tubes. It is manifest that each tube must deliver a constantly uniform volume of fluid without accumulation of a variably sized hanging drop about its opening during, or subsequent to, delivery. This was eliminated by altering the tip and opening the nozzle of the tube, and by polishing its end on a very fine oil stone, thereby eliminating the need of dipping it into oil. Failure to observe these precautions will lead to unequal and, therefore, inaccurate deliveries.

ACCURACY OF DELIVERY BY MACHINE

The accuracy of the pipetting machine was determined by weighing 10 successive deliveries of 1.0 c.c. water from each of four syringes. Table I shows the recorded weights of these deliveries at a constant temperature of 20° C., as determined on a Christian-Becker chain-o-matic balance. These figures indicate that the individual delivery from each pipette did not vary more than two parts per thousand, thus indicating the very high degree of each individual delivery with the pipetting machine. If even greater accuracy in the deliveries of all syringes is desired, four syringes of exact dimensions must be employed. These can be obtained only by selection from a large number of syringes by trial weighings of individual deliveries under standard conditions.

TABLE I
WEIGHT IN GRAMS OF SUCCESSIVE DELIVERIES OF SYRINGES

	SYRINGE 1	SYRINGE 2	SYRINGE 3	SYRINGE 4
	1.0048	1.0069	1.0024	0.9989
	1.0010	1.0025	1.0007	0.9973
	1.0012	1.0054	1.0024	0.9980
	1.0025	1.0042	1.0000	0.9965
	1.0045	1.0035	1.0035	0.9964
	1.0049	1.0025	1.0000	0.9971
	1.0018	1.0023	1.0011	1.0009
	1.0062	1.0050	1.0000	0.9998
	1.0050	1.0027	1.0015	1.0019
	1.0033	1.0029	1.0009	0.9988
Average weight	1.0035	1.0039	1.0012	0.9985
Mean deviation	0.00156	0.00129	0.00095	0.00150

Extensive experiments with pipetting by hand carried out under conditions identical with those for the test of the accuracy of the pipetting machine show that the maximum error is in the second significant place and lies between 0.9372 and 0.9982. This maximum percentage error of six parts per hundred, or 6 per cent, compares unfavorably with the maximum deviation of two parts per thousand, or 0.2 per cent, obtained with the automatic pipetting machine. This may be a significant source of error in that, with the pipetting of complement and antigen by hand in the New York State quantitative complement fixation test for syphilis, the possible cumulative error may rise to a total of 12 per cent. It is also of interest to note that all deliveries by hand were below 1.0 c.c., for which the pipettes were standardized. In the actual performance of the test, this would represent a second significant source of error in that smaller amounts of reagent are added than are required, thereby increasing the experimental error.

CARE OF THE MACHINES

The normal use of the automatic quadruple pipetting machine requires only a general lubrication of its moving parts when necessary, and flushing of the syringes and rubber tubing system with distilled water. The intake tube is immersed in distilled water, and by inserting a spatula beneath the plunger of the syringe and moving it up and down for about 20 full strokes, the

system is thoroughly flushed out. The intake tube is now removed from the distilled water, and with a few additional strokes of the plunger of the syringe, the system is emptied. The valve block need not be disassembled unless there is accumulation of foreign material on the valve seats, but this is extremely uncommon.

ADVANTAGES OF AUTOMATIC QUADRUPLE PIPETTING MACHINE

The advantages of the pipetting machine consist in the elimination of all adjustments after its first setting, increased speed and higher precision in the delivery of measured small amounts of fluid reagents, and absence of fatigue of the operator in comparison with pipetting by hand. In addition, there is a complete elimination of breakage and cleansing of serologic pipettes. The time required for the delivery of antigen and complement in various dilutions, salt solution, and sensitized sheep red blood cells in the New York State quantitative complement fixation test for syphilis is considerably reduced and accomplished with increased accuracy.

SUMMARY

An automatic quadruple pipetting machine for the accurate and rapid dispensing of liquids in amount of 0.05 c.c. to 0.2 c.c. in the New York State quantitative complement fixation test for syphilis is described. Its operation for over one year in our laboratory has given eminent satisfaction. The instrument can be readily adapted to other laboratory methods. For the delivery of larger amounts of fluid, larger syringes may be substituted.

The machine is manufactured by the Curtin-Hebert Co., Inc., Gloversville, N. Y.

THE DETERMINATION OF SENSITIVITY TO PAIN

A SIMPLE CLINICAL METHOD

LOUIS PELNER, M.D., BROOKLYN, N. Y.

ALL who have read Emanuel Libman's¹ classical essay on the individual sensitiveness to pain must realize that without an appraisal of a patient's susceptibility to pain, there cannot be adequate diagnosis, prognosis, or treatment. The hyposensitive patient's complaints must be magnified in order to obtain a proper perspective. According to Libman,¹ a hyposensitive patient feels less pain, and the pain that he does feel has an unusual radiation. He may have substitution symptoms, e.g., pressure, burning, or numbness instead of pain. Every clinician can probably recall a case or two of a very acute surgical abdomen, where the surgeon was not consulted early because the patient did not have real pain, but had instead burning, pressure, or numbness over the abdomen. Libman believes that in the case of the hyposensitive patient, the pain impulses are delayed in the autonomic nervous system, while in the case of the hypersensitive patient, the impulse travels more directly to the central nervous system. He thus explains the occurrence of yawning, coughing, choking, and sneezing instead of pain in the hyposensitive patient.

There are many methods for measuring the intensity of the stimulus required to cause pain in the skin of a person. It is naturally assumed that the induced pain acts in the same way as a spontaneous pain. Roughly, the methods for inducing this stimulus are as follows: thermal, electrical, chemical, and mechanical. The thermal method was first used by Goldscheider in 1884, and has recently been made extremely accurate by Hardy, Woolf, and Goodell.² The drawback is the extensive equipment and the time necessary to determine the pain threshold of a person. It thus will have limited use except in a physiologic laboratory. The excellent papers of Hardy and co-workers show how well this method can be used on a small scale. The electrical method consists of stimulation of the skin with a faradic current and measuring the amount that will cause pain in a person. The exponents of this method who have done important work are Helmholtz, Martin,³ Macht, Hauck and Neuert. The chemical method has been inadequately studied, possibly because stimulation by this method might cause an actual change in the skin. The mechanical method has been studied by von Frey, Eddy,⁴ and others. Libman's test is an example of this method. In this test the examiner's thumb is pressed against the styloid process of the patient. This allows for a rough estimation of the person's sensitivity to pain. It can easily be seen that one factor in this test would be the strength of the examiner. There is, furthermore, an occasional difference between styloid processes. Recently Hollander⁵ suggested an ingenious

instrument that consists of a grater sewed to a blood pressure cuff. The cuff is applied in the usual way to the patient's arm and the cuff is inflated. The end point is reached when the patient cries out or winces. According to the most recent work,⁶ this method is not considered accurate in obese or in moderately obese patients, and in those with severe or moderate hypertension. These restrictions limit the usefulness.

The instrument used in this study, the sensometer, is also a mechanical method of inducing pain in the skin. The one common drawback of the mechanical method is that the deformation and internal stresses of the skin and underlying tissues are not taken into account. In the method herein described, a part of the body is chosen that is not obese; it is felt that this reduces a serious drawback to the pressure method.

Fig. 1.

A NEW METHOD OF ESTIMATING PAIN SENSITIVITY

The device used in this study can be called a sensometer (Fig. 1). It is adapted easily from an instrument called the Geneva Lens Measure and is procurable as such all over the world. It consists of two peripheral fixed points, and one central point, which is attached to a hand on a watch dial. Originally the two fixed points were 2 cm. apart. These have been altered so that they are now 7 mm. apart. This can be done by the local watchmaker or jeweler. The reason for the alteration is that a flat surface is preferable for application of the stimulus, and it is difficult to find an area of the body that is flat for this distance (2 cm.). Also, too many nerve endings may be stimulated if the points are separated too widely; this may cause summation of impulses. However, readings are approximately the same with either measurement.

A relatively flat, nonfleshy portion of the body is chosen for this test. To insure uniformity in the survey, we have used the proximal phalanx of the

thumb held horizontally with the distal phalanx bent at right angles to it. The sensometer is rested on the phalanx, and the number that it registers of its own weight is kept in mind. Then the instrument is pressed into the skin until the pain becomes unbearable, and the number corresponding to this sensation is read. As one presses the two fixed points harder into the skin, the central point moves an equal distance, and this is measured on the dial. The difference between the figure read before and after pressure on the skin is taken as the patient's pain sensitivity. This instrument is standardized the same way all over the world. It can be tested before using by putting it on a perfectly flat surface; the watch hand will then read zero. In many months of constant use there has been no need for repair of the instrument.

DISTRIBUTION OF SUBJECTS

Fig. 2.

FINDINGS

A total of 178 patients and colleagues were tested repeatedly with the sensometer according to the method described. Each patient was also tested by the Libman method for comparison. The distribution of the results is indicated in Fig. 2. Hypersensitive patients represent about 22 per cent of the total tested, which agrees with the Libman figure of 30 per cent. Except for several minor variations, the Libman test agrees rather well with this study. The majority of the cases that were Libman positive (hypersensitive), ran from 0 to 3.5 units on the sensometer. The Libman negative cases (hyposensitive), with few exceptions, were over 3.5 units on the sensometer. It is in determining the degree of hypersensitivity or hyposensitivity that we feel that this method is superior to the Libman test.

There were 18 patients who deserve separate mention. Eight were positive to the Libman test on one side and negative on the other. Three of these, in spite of being hyposensitive, had had otitis media in their youth, which may account for a tender styloid process. Ten were unusual in one respect, al-

though the agreement between the sensometer readings and the Libman test matched closely. These were neurasthenic individuals, where one would expect a low score and highly positive Libman test, but where the reverse was true. These patients were Libman negative and had a high sensometer rating, but in each the feeling of pain induced by the stimulus lasted from twenty to thirty minutes to several days. Other neurasthenic individuals had low sensometer readings and highly positive Libman tests, but here also the sensation was prolonged. Normally, the feeling of pain caused by the pressure stimulus in either test lasted at most only two to three minutes.

One might postulate a theory from these facts as to the exaggeration of symptoms in certain neurasthenic individuals. There must be constant reinforcement of the stimulus in a neurasthenic individual, perhaps something in the nature of recurring afterimages. This may be caused by lack of certain substances in the body. Wilder⁷ has recently restated a well-known fact that pellagrins cannot stand much pain; they feel this pain, however slight, for a long time, its disappearance coming only after adequate nicotinic acid therapy. This suggestive lead is given for research in the pain sensation of some neurasthenic individuals.

Eight patients were hypothyroid individuals. The basal metabolic rates ranged from minus 25 per cent to minus 9 per cent. The sensometer readings were high, some of the highest being in this class. The Libman test agreed very accurately with these readings. Whether these readings were actually high, or whether they were due to a slower perception and slower reaction time, merits separate investigation.

SUMMARY

1. A method of estimating the individual's susceptibility to pain is described.
2. This method is compared to the Libman test and a fairly close correlation is reached.
3. Pain sensitiveness in neurasthenic and hypothyroid patients is briefly analyzed.

A TUBE FOR THE CENTRIFUGATION OF SIXTEEN SPECIMENS IN A FOUR-PLACE CENTRIFUGE*

FREDERIC E. HOLMES, M.S., CINCINNATI, OHIO

IN LABORATORIES in small hospitals serving large normal populations, the so-called "clinical centrifuge" is adequate for all ordinary purposes, but it may become the "bottle neck" in laboratory procedure in unusual circumstances, prolonging the day's work far beyond the time required by the other operations in the methods, and sometimes resulting in loss of unstable constituents. In a recent survey of vitamin C levels in the plasma of children in an orphanage, the "10 mm. centrifuge tube" shown in Fig. 1 eliminated this difficulty.

Fig. 1.—A 10 mm. centrifuge tube (left) and the arrangement of seven tubes in a 50 ml. brass centrifuge cup (right).

The International clinical centrifuge accommodates a four-place head having two 15 ml. and two 50 ml. brass cups, which can be purchased separately if the machine is not already equipped with it. One 10 mm. centrifuge tube can be placed in each 15 ml. cup, and seven 10 mm. tubes in each 50 ml. cup. Thus sixteen specimens may be centrifuged at one time. (If flat rubber pads are not at hand for the bottoms of the 50 ml. cups, they can be made by cutting a section from the middle of a No. 6 rubber stopper.)

Although the 10 mm. centrifuge tube was designed for use with the clinical centrifuge having a four-place head, it offers several advantages when used with the larger centrifuge and the eight-place head. Fourteen tubes containing specimens can be balanced in one operation instead of in seven. The depth

*From the Children's Hospital Research Foundation, and the Department of Pediatrics, College of Medicine, University of Cincinnati, Cincinnati.
Received for publication, February 21, 1941.

of the supernatant fluid makes it easier to draw off plasma without disturbing the cells. Exposure of the specimen to air is less, whether stoppered or unstoppered. The tube accommodates 4 ml., which is sufficient volume of specimen for many determinations for which blood is taken. It is sufficiently cheap and durable to be used for collection of the specimen, and the volume of specimen is easily estimated (approximately 1 ml. per inch).

The tubing selected for these centrifuge tubes must be between 9.5 and 10.0 mm., *preferably between 9.6 and 9.8 mm. in outside diameter.* The larger limit is the maximum which will permit the tubes to be easily placed in the 50 ml. cups, and the smaller limit insures room enough for inserting the tip of a transfer pipette or a 1 ml. graduated pipette. One end is sealed off as shown, and the tube is cut to a length of 110 mm. and fire-polished. (120 mm. is permissible for use with the larger centrifuge heads.) The end should be smoothly rounded and thick for mechanical strength. Tapered ends similar to those of the ordinary 15 ml. centrifuge tube were tried, but this offered no advantage and was even detrimental in operations in which the precipitate was to be resuspended, such as the washing of cells.

THE LAKING OF GLYCERINATED RED BLOOD CELLS BY PHYSIOLOGIC SALT SOLUTION*

HAROLD H. MITCHELL, B.S., M.S., ST. LOUIS, MO.

PERFORMING the Wassermann reaction with high titer amboceptor serum, containing 50 per cent glycerin as a preservative, presents no complications. However, with an amboceptor serum of low titer we encountered a complication which was due to the contained glycerin. After the red blood corpuscles had remained in contact with the relatively large amount of amboceptor serum (necessitated by its low titer) for an hour or longer, they were subject to immediate lysis when added to 0.85 per cent salt solution.

Inquiry revealed that this phenomenon was due to the slow diffusion of glycerin into the red blood corpuscles. The osmotic pressure developed upon introduction into the glycerol-free normal salt solution caused sudden lysis of cells. This degree of osmotic change occurs if the amount of amboceptor necessary to sensitize a given volume of cells results in addition of such an amount of glycerin that its final concentration in the cell suspensions reaches 2 per cent or more.

The glycerinated cells could be brought back to normal stability by washing in hypertonic salt solution or by addition of normal salt solution very slowly in divided amounts.

It is suggested that low titer amboceptor be preserved by some means other than glycerin, or that cells subjected to a large amount of glycerin be suitably washed before use.

A RAPID METHOD OF DEHYDRATING AND CLEARING IRON-HEMATOXYLIN STAINED FECAL SMEARS*

B. W. SHERIDAN, WASHINGTON, D. C.

THE preparation of wet-fixed stained smears for the identification of intestinal protozoa is a time-consuming procedure and is, therefore, considered by many impractical for clinical laboratories. Any modification which shortens the methods used should be of practical interest.

I have found that a preparation called cellosolve (ethylene glycol monoethyl ether) can be used for dehydration and clearing instead of alcohol and xylol, and thereby a considerable amount of time can be saved. Instead of the eight changes usually used for the dehydration and clearing with alcohol and xylol, only a single immersion of ten minutes in cellosolve is required.

The use of cellosolve also has the advantage of being less expensive. A dehydration-clearing set-up of alcohol and xylol (eight dishes) costs about \$1.30, while the cost of a dish of cellosolve for the same purpose is less than 20 cents. Furthermore, the cellosolve can be used longer and for a greater number of smears before losing its efficacy.

By using a short method of staining, as suggested by Johnson,¹ the whole procedure of fixing, staining, dehydration, and clearing can be accomplished in about an hour.

The timing of the various steps in the method now used at the United States Naval Medical School is as follows:

Fix in Schaudinn's solution (glacial acetic acid to strength of 5 per cent added)	5 minutes.
Alcohol, 95 per cent, with iodine to a port wine color	3 minutes.
Alcohol, 70 per cent	3 minutes.
Rinse in tap water.	
Ferrie ammonium sulfate, 4 per cent	15 minutes.
Rinse in tap water.	
Hematoxylin, aqueous solution, 0.5 per cent	10 minutes.
Ferrie ammonium sulfate, 0.25 per cent	12 minutes.†
Wash in running water	1 minute.
Cellosolve	10 minutes.
Mount in balsam.	

The foregoing method has now been used for a year and has been found entirely satisfactory in the routine work of identifying the intestinal protozoa. As far as can be determined at this time the stains are as permanent as those dehydrated and cleared in alcohol and xylol.

AN IMPROVED METHOD FOR THE ESTIMATION OF QUANTITATIVE AND QUALITATIVE PLATELET FACTORS*

HEYWORTH N. SANFORD, M.D., AND ELEANOR I. LESLIE, M.D.
CHICAGO, ILL.

IN 1936 we described a method for the quantitative and qualitative estimations of platelets in their own plasma.¹ During the past five years we have shortened and simplified this method until we now believe that it may be easily and simply done in any laboratory.

METHOD

No anticoagulants are used since such substances mask the extent to which platelets may be broken down in the original blood sample and so interfere with the correct judgment of results. This test requires 1 c.c. of blood, withdrawn from a vein into an iced, oiled syringe, and introduced into a paraffined tube imbedded in ice. We have found that the graduated 1 c.c. tubes used for sedimentation time are excellent for this purpose. These tubes are paraffined with a mixture of two-thirds paraffin and one-third mineral oil. The tubes are then packed in ice in a large centrifuge cup and centrifuged for one and one-half minutes at 5,000 r.p.m..

After one and one-half minutes centrifuging the platelet count is made as follows: A few grains of heparin are placed on a watch crystal which has been thoroughly chilled, and resting in ice. A sample from the center of the centrifuged plasma is drawn up into a capillary tube, and several drops are mixed with the heparin. Following thorough mixing, a drop of this mixture is placed in a chilled counting chamber, covered with a chilled cover glass, and placed in a refrigerator or under ice for fifteen minutes to allow for settling. The platelets in 80 small squares are then counted, and the results are multiplied by 50 to obtain the number of platelets in a cubic millimeter (the platelets in the 80 small squares represent $\frac{1}{50}$ c.mm.). The platelet counts obtained by the method described must be considered as plasma platelet counts and should be further corrected for whole blood. This is obtained by the hematocrit reading obtained later. The plasma platelet count multiplied by the plasma percentage gives the platelet count for the whole blood.

At the same time that the plasma is placed on the watch glass for the platelet count, the remainder of the plasma left in the capillary tube is used to estimate the coagulation time of the plasma. This is done by breaking off pieces of the tube, as in the method of Rudolph, until a thread of plasma has formed. This represents the coagulation time of the platelet containing plasma,

*From the Department of Pediatrics, Rush Medical College, and the Presbyterian Hospital, Chicago.

Funds for the last year of this study were given by the Elizabeth McCormick Child Research Grant.

Received for publication, March 3, 1941.

and is designated plasma A. As soon as the capillary tube of plasma is withdrawn from the original paraffined tube containing the blood sample, the latter is again placed in ice and centrifuged for fifteen minutes. At the end of this time another sample of the centrifuged plasma, which is now platelet free, is taken into a capillary pipette and the coagulation time is obtained as before. This plasma is designated plasma B. The hematocrit reading may now be made for calculation of the total platelets in the blood sample.

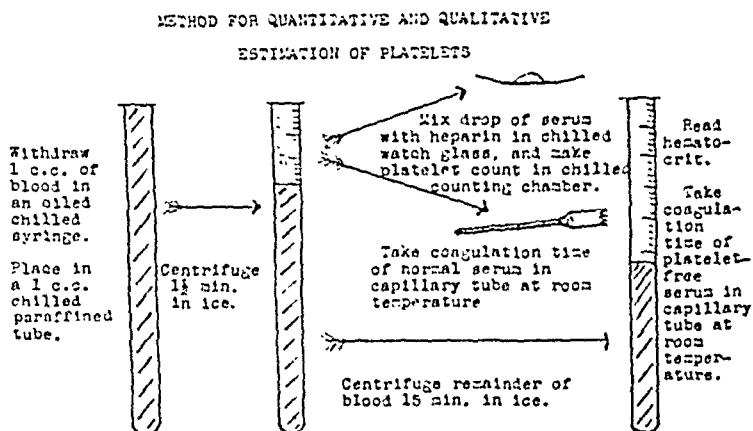

Fig. 1.

The principal changes from our original method reported in 1936 are the elimination of all time-consuming processes dealing with plasma fractions which we do not believe are clinically necessary. Also in shortening the centrifuging of the plasma for fifteen minutes instead of one and one-half hours as formerly used, we have reduced the time so that the entire estimations may be done in twenty minutes. It must be understood that values for plasma B depend on the length of time taken in centrifuging. The longer the plasma is centrifuged, the more platelets will be thrown down, and conversely, the longer will be the coagulation time of this plasma. Fifteen minutes was taken as the time for this centrifuging because it is the shortest time in which all microscopically visible platelets can be centrifuged from the plasma. It would be well before undertaking this test for each worker to test his individual centrifuge by observing if there were any platelets in the plasma after fifteen minutes of centrifuging.

With this procedure we have for consideration a plasma platelet count, the coagulation time of natural plasma with its full number of platelets, and the coagulation time of platelet-free plasma. It must be emphasized that if any difficulty is encountered in obtaining the blood so that there is the slightest addition of tissue fluid or cerebrospinal fluid, the results are unreliable. This can be immediately detected by the platelet count. It will be lower than anticipated, and the platelets will show clumping and variation in size. Any platelet count of less than 100,000 should be viewed with suspicion and repeated. If the procedure is carried out under these conditions, one of two things will occur. First, all the coagulation times will be abnormally short, or plasma B may even coagulate in the centrifuge tube. This should be suspected if plasma A coagulates in less than four minutes. Secondly, in the opposite extreme all

coagulation times may be abnormally long, and plasma B may never coagulate because coagulation has occurred and the supernatant fluid is serum rather than plasma. This is noted especially if cerebrospinal fluid is allowed to get into the sample. This difficulty would probably not occur in obtaining blood from adults, but in pediatric work in newborn and small infants blood is frequently withdrawn from the longitudinal sinus, where cerebrospinal fluid is very easily drawn in with the blood. It is very important, therefore, to know if there have been such additions to the blood. This method of checking is far from perfect, but when anticoagulants are used, no check at all is possible.

RESULTS

Normal adults show a plasma platelet count varying between 100,000 and 400,000 per c.mm. The coagulation time for the normal plasma (plasma A) is between four and eight minutes, and for platelet-free plasma (plasma B) between six and ten minutes.

The first deviation from these standards is shown in individuals with hemorrhagic symptoms, but with a normal or higher platelet count. We have found this in the following conditions:

1. Hemophilia. This condition will show values for plasma A and plasma B of from ten to twenty times the normal value. Following transfusion, plasma A will drop to long normal values, but plasma B will still remain long, even during periods that are hemorrhage free. In one instance in a child, aged 1 year, in which the maternal uncle has hemophilia, the platelets were 360,000 with a coagulation time of twenty-four minutes for plasma A and twenty-seven minutes for plasma B. This boy has had some petechial hemorrhages and large ecchymotic areas after small bruises, but no gross hemorrhages have occurred. We feel that the diagnosis of hemophilia is justified in this instance.

2. Pathology of the liver and gall bladder, or bleeding with jaundice. This can be divided into two groups:

- a. In which a deficiency of prothrombin also occurs. In these instances both plasma A and plasma B will be somewhat prolonged in proportion to the level of prothrombin. Our ratio has been as follows:

Prothrombin 30 per cent,	plasma A 10,	plasma B 11
Prothrombin 40 per cent,	plasma A 9,	plasma B 11
Prothrombin 50 per cent,	plasma A 8,	plasma B 10
Prothrombin 60 per cent,	plasma A 6,	plasma B 7
Prothrombin 70 per cent,	plasma A 6,	plasma B 6

- b. In which the prothrombin is of normal value. In several instances we have found an increase in both plasma A and plasma B values with relatively normal prothrombin. For example, in a carcinoma of the gall bladder region, the coagulation time for plasma A was twelve minutes, and that for plasma B was fourteen minutes; the prothrombin value was 75 per cent.

3. A very small group, which except in one instance was characterized by intestinal bleeding, is that in which the platelets are normal or even higher than normal with slightly increased values for plasma A but considerable increase for plasma B. The prothrombin was normal in all instances. With the one exception of an endocarditis with petechial hemorrhages, the remaining four in this group had intestinal bleeding. Three were considered to have

ulcerative colitis. The fourth was a boy whom we have followed for several years, whose case has been diagnosed as Henoch's purpura. In one instance when he was seen immediately after a very severe bleeding from the bowel, his blood showed 325,000 platelets, his plasma A had a coagulation time of nine minutes, and his plasma B eighteen minutes. Since all these patients had normal platelet counts, the delayed coagulation time would seem necessarily due to an increased platelet resistance.

The second and by far the larger group deviating from normal is that in which the platelets are less than normal. We consider this to be the case when the platelets are less than 100,000 by this method.

1. This group includes those with anemias, leucemias, and infections that affect the blood stream. These are all characterized by a thrombocytopenia, proportional increase of coagulation time in both plasmas A and B, and a low hematocrit. We felt that one should never make a diagnosis of primary thrombocytopenia with a low hematocrit. It is almost certain to be of a secondary type. Examples of these are aplastic anemia: Platelets 24,000; plasma A coagulation time nine minutes; plasma B, fifteen minutes; hematocrit 10 per cent; marked hemorrhage. Leucemia: Platelets 124,000, plasma A coagulation time seven minutes; plasma B, eight minutes; hematocrit 40 per cent; no bleeding. Same child when platelets were 23,000: plasma A coagulation time eight minutes; plasma B thirteen minutes; hematocrit 25 per cent; marked hemorrhages. Infected mastoid (*streptococcus*): platelets 40,000, plasma A coagulation time eight minutes; plasma B, fifteen minutes; hematocrit 30 per cent; ecchymosis and petechiá. After transfusion the platelets were 180,000, plasma A coagulation time was five minutes, plasma B was seven minutes, and hematocrit was 40 per cent.

The findings in these cases of thrombocytopenia suggest that in this group we are dealing with platelets which, though reduced in number, are fairly normal in character. They undergo relatively little disintegration during the process of centrifuging them out of the plasma, and the coagulation time of plasma A is prolonged in most cases, proportionally to the reduction in total platelet count.

2. Thrombocytopenia, with increased coagulation time of plasmas A and B, but with these practically equal in time. The majority of these individuals have had petechiae and hemorrhages in different parts of the body over a long period of time. A ten-year-old girl had petechial hemorrhages, and bleeding from the mucous membranes for five years: platelets 5,000; plasma A coagulation time eighteen minutes; plasma B, eighteen minutes. A 13-year-old boy had similar symptoms and bleeding over a period of three years, with several transfusions: platelets 4,000; plasma A coagulation time, twenty minutes; plasma B, twenty-two minutes. Following transfusions with increases in the platelet count, plasma A will shorten to almost normal, while plasma B will remain at double the normal coagulation time.

In this group we are dealing with longer standing hemorrhagic disturbances, resembling the syndrome described by Werlhof. Here the platelets do not show a normal resistance but are broken down during centrifugation, yielding a platelet-free plasma which coagulates as rapidly as the normal plasma (plasma A).

3. Thrombocytopenia, with long normal coagulation time, and only occasional hemorrhagic symptoms. Persons of this group have occasional petechiae and small areas of ecchymosis, with some very slight bleeding of the mucous membranes. Their platelets vary from 5,000 to 50,000; their plasma A coagulation time is from four to ten minutes, and their plasma B, from nine to eleven minutes. Their hematocrit, prothrombin, and vitamin C blood content are all normal. We have called such instances "congenital thrombocytopenia," and described a family in such a state in 1936.² Since that time we have found twelve more such patients, but have been unable to trace any family connection as in the first family. It will be noted that while their normal plasma coagulates normally, their platelet-free plasma is a little longer than normal. This would indicate that their platelets are very active and that coagulation time is delayed only because of a failure in gross number. Such individuals do not have fatal hemorrhages because their platelets disintegrate more rapidly than do normal platelets. However, some factors might occur that would reduce or lessen this ability to disintegrate and cause a profuse hemorrhage. As long as no exceptional stress or strain is put on persons with this condition, they are able to have normal blood-clotting functions, but in the presence of an acute infection or debilitating condition, the increased power of disintegration of the platelets is lost and a profuse hemorrhage may occur.

One of the most interesting findings to us in this study is the fact that the gross quantity of the platelets in the blood does not seem to make a proportional difference in the coagulation ability of the blood or plasma. Platelet counts of 100,000 to 400,000 will all show approximately the same coagulation values. Even if the platelet value is reduced below 100,000 there is not a great deal of change until the number is decreased below 30,000. We have found individuals with platelet counts of 5,000 and only slightly increased coagulation values. On the other extreme we have hemophilias with platelet values of 500,000, with practically no blood coagulation at all. We have come to pay very little attention to the gross quantitative platelet value, but use it simply as a check on our technique. As stated before, the admission of even the smallest quantity of tissue fluid or cerebrospinal fluid to the blood will decrease the platelet number and give faulty coagulation values. A platelet value of less than 100,000 should be thoroughly rechecked. We believe, therefore, that the most important function of the platelets is not their number or quantity, but their activity or disintegration ability. This can be demonstrated by the coagulation of the plasma fractions as described.

SUMMARY

A clinical method for the estimation of platelets quantitatively and qualitatively in their own plasma, without the use of anticoagulants, is described.

CHEMICAL

PEPTONE IN PROTEIN HYDROLYSATES AND AMINO ACID MIXTURES*

K. S. KEMMERER, PH.D., AND G. P. HEHL, B.S.
EVANSVILLE, IND.

INTRODUCTION

HYDROLYTIC reagents split protein materials into molecular units of various size. Such degradation products have been classified, supposedly in the order of their molecular weight, as protein, metaprotein, proteose, peptone, subpeptone, and amino acids. Classification is based in part on solubility behavior and reactions which certain hydrolysates display toward reagents.

The peptone fraction of hydrolysates has been the subject of much discussion. Products designated as "peptone" are widely used as a medium for bacterial growth, in jejunal feeding, and in some supposedly therapeutic diets. But even completely hydrolyzed proteins have been decried for parenteral use because of possible "peptone" shock. However, the factor responsible for the production of shock has never been fully established. Two classes of materials have been incriminated: peptone itself, and by-products resulting from the hydrolysis. It has been the common observation that Witte's peptone produces shock¹ or some phase of the shock phenomenon.^{2, 3} Thus Henriques and Andersen⁴ observed no shock from the parenteral injection of enzymatically hydrolyzed meat protein, yet the injection of Witte's peptone resulted in the death of his animals. Likewise, Milles and Seed⁵ gave repeated injections of Difco's bacto-peptone to dogs and were unable to detect any toxic effects. It is thus evident that some peptones produce shock and others do not. It is quite possible that the method used to prepare peptone products is largely responsible for their shock-producing quality, and that "peptone" itself need not necessarily be involved.

It is difficult for the chemist to define what is meant by peptone. The term is a vague one, and though it has been commonly used for years, it does not seem to denote a chemical entity. The several proposals which have been made for its quantitative estimation involve its precipitation from aqueous solution. The earlier procedures utilized phosphotungstic acid as the precipitant, but these methods are now recognized as unreliable due to the partial precipitation of certain basic amino acids which are usually present in the solution. The use of bromine⁶ as a precipitant for peptone was discarded at an early date when it was demonstrated that such treatment resulted in the loss of nitrogen. Gubareff and Sergejewa⁷ utilized the biuret reaction for estimating peptone after the solution had been heated to coagulate unhydrolyzed protein.

*From the Laboratories of Mead Johnson & Co., Evansville, Ind.
Received for publication, April 9, 1941.

Such a procedure is unsatisfactory, since it will include all substances not coagulated by heat that give a positive biuret reaction. Schjerning⁸ outlined a procedure utilizing tannic acid as the precipitant for the peptone fraction. Bigelow and Cook⁹ improved his early technique and claimed that if a correction for creatinine (precipitated by tannic acid) was made, good results could be obtained. They found that a low temperature and a definite concentration of tannic acid and salt were necessary for maximum precipitation of peptone nitrogen. After a careful study of the factors affecting the precipitation of peptone by tannic acid, Wasteneys and Borsook¹⁰ outlined a method for its estimation in enzymic digests of protein under carefully controlled conditions. This is the only available and dependable method for the determination of peptone, and in the experiments below we have followed their outlined procedure.

EXPERIMENTAL

An acid and an enzymic digest of casein, a mixture of crystalline amino acids, and Difco's bacto-peptone were studied for their peptone content.¹⁰ The enzymic digest was prepared in a manner previously described.¹¹ The acid digest was prepared by boiling casein in 25 per cent sulfuric acid and then carefully neutralizing the sulfuric acid with barium hydroxide. The filtrate was decolorized and dried to a fine powder in an atmospheric spray dryer. The mixture of crystalline amino acids contained twenty of the twenty-three usually accepted amino acids in the amounts used by Shohl and Blackfan.¹² Hydroxyglutamic acid, thyroxine, and diiodotyrosin were omitted. Difco's bacto-peptone, as purchased, was the fourth substance.

None of the four substances contained protein or proteose, since they gave no precipitate with trichloroacetic acid or when the solution was saturated with sodium sulfate. The solution was prepared for the peptone determinations by dissolving 10.0 Gm. of the dry powder in 100 c.c. of 22 per cent sodium sulfate solution, adjusting the pH to 7.0 by the addition of a few drops of 60 per cent sodium hydroxide, and diluting to a volume of 200 c.c. with the sodium sulfate solution. To 25 c.c. aliquots were added an equal volume of 2.21 N sodium hydroxide and 125 c.c. of 20 per cent tannic acid dissolved in 0.1 N sulfuric acid containing 20 per cent sodium sulfate. The mixture was thoroughly shaken and kept at 20° C. for four hours. The solution was then filtered and nitrogen determinations were made on the filtrate. All determinations were run in triplicate by the Kjeldahl-Gunning method, and suitable correction made for the nitrogen content of the reagents. The difference between the initial nitrogen content of the original solution and the nitrogen content of the filtrate is expressed as the percentage of peptone nitrogen precipitated.

The results obtained are given in Table I. The apparent peptone content of the enzymic hydrolysate was 26.9 per cent, since this amount of the total nitrogen was precipitated by the tannic acid. The acid hydrolysate gave a figure closely approximating this, i.e., 22.73 per cent. Most surprisingly, the mixture of crystalline amino acids showed an apparent peptone content of 21.36 per cent. These average findings are all so closely similar that they raise the question as to whether all three preparations contain the same amount of peptone, or whether there is any peptone present at all.

It is evident that there is no peptone in a mixture of pure crystalline amino acids. Also, it is generally believed that prolonged boiling with strong acid reduces complex nitrogenous molecules almost entirely to the state of amino acids. At most, some dipeptide linkages may be present. We are, therefore, left with the finding that a mixture known to consist solely of amino acids, and a second mixture known to consist predominantly of such groups, but with possibly some dipeptide linkages, have essentially the same apparent peptone content of 21 to 23 per cent. The conclusion is obviously untenable. The observed differences, if they mean anything at all, do not represent anything in regard to peptone, and at most may represent differences in the amino acid content of the different substances employed.

TABLE I

PRECIPITATION OF NITROGEN FROM PROTEIN HYDROLYSATES AND AMINO ACID MIXTURE

SUBSTANCE	TOTAL NITROGEN			NITROGEN PRECIPITATED (%)
	IN ORIGINAL ALIQOT (MG.)	IN FILTRATE (MG.)	NITROGEN PPT. (MG.)

	184	47	137	74.46
Average	—	—	—	74.21

DISCUSSION

The report demonstrates the difficulty of arriving at any conclusion on the peptone content of the various materials. A mixture of crystalline amino acids, an acid hydrolysate of casein, and an enzymic digest of casein have been shown to have an apparent peptone content of 21, 23, and 27 per cent, respectively.

The differences in the apparent peptone content of the three widely different substances were not large and can be accounted for solely on the basis of the variability of the method itself. It thus seems impossible to determine what meaning may be attached to the finding that 74 per cent of the nitrogen of a preparation reportedly containing peptone is precipitated by tannic acid.

On the other hand, the precipitation of 74 per cent of the nitrogen of bacto-peptone indicates something. This larger amount of precipitated nitrogen cannot logically be explained on a basis of differing amino acid composition. It probably represents, in part, the presence of some larger molecular units. It seems quite possible, however, that it may not all be representative of such larger units. Nor would it seem advisable to use the figure 21.4 obtained for the mixture of crystalline amino acids as kind of blank for other approximations of peptone, since it can be interpreted from our findings that the amount of nitrogen precipitated by tannic acid depends to some extent on the percentage composition of the particular amino acid mixture used. The mixture of Shohl and Blackfan¹² may or may not approximately represent the composition of the digests, even though their mixture was designed to simulate the composition of casein. The acid digest which we employed contained no tryptophan, and certain portions of other amino acids may have been lost by adsorption on the precipitated barium sulfate. The enzymic digest, although probably containing most of the casein nitrogen, contained in addition a certain amount of nitrogen from the pancreas. We are thus left in doubt as to the significance of the concept of peptone.

SUMMARY

Precipitation with tannic acid is the only currently employed method for the estimation of peptone. The procedure results in the precipitation of 21 per cent of the nitrogen of a mixture of crystalline amino acids, 23 per cent of the nitrogen of an acid hydrolyzed protein, 27 per cent of the nitrogen of an enzymic digest of protein, and 74 per cent of the nitrogen of bacto-peptone. The method cannot be regarded as at all definitive for peptone.

SIMPLIFIED CALCULATION AND NOMOGRAM OF THE VAN SLYKE UREA CLEARANCE TEST*

J. E. HEESTERMAN AND S. TILLEMA
DUTCH GUIANA, S. A.

DURING the last decades there has been an increasing interest in the functional capacities of diseased organs. This has given rise to various functional tests. One of the most important of these has been the Van Slyke urea clearance test for renal function. This test has almost generally been accepted as most reliable and has become a routine test in many hospitals. Van Slyke's formula is:

$$\frac{U}{B} \sqrt{C}$$

where U = urea content of urine, B = same of blood, C = urine output in one minute. C is calculated by dividing the output for one hour, H , by 60. The result is expressed in per cents of 54, this being the average value in healthy people. The actual calculation, therefore, is:

$$\frac{U}{B} \sqrt{\frac{H}{60}} \times \frac{100}{54}.$$

To reduce the daily loss of time in calculating this formula we used the transposition:

$$\begin{aligned} \frac{U}{B} \sqrt{\frac{H}{60}} \times \frac{100}{54} &= \frac{U}{B} \sqrt{H} \times \frac{100}{54 \sqrt{60}} = \frac{U}{B} \sqrt{H} \times 0.2391 \\ &= \frac{\sqrt{H}}{B} \times 0.2391 U = \frac{\sqrt{H}}{B} \times 0.24 U. \end{aligned}$$

Substituting 0.24 for 0.2391 gives an error of only 0.4 per cent, negligible in routine work. This can be read on a slide rule in a few seconds. However, since medical men in general are not acquainted with the use of a slide rule, we have drawn up a nomogram by transposing the formula to read thus:

$$\frac{U}{B} \times 0.2391 \sqrt{H}.$$

To read the nomogram the figure representing the urea content of the urine and the figure representing the blood urea are connected by a straight line. (A

*From the Paramaribo Medical School, Dutch Guiana.
Received for publication, March 27, 1941.

black thread is most suitable.) The point of intersection of this line and the U/B line is connected with the figure representing the urine output in one hour. The point of intersection of this second line and the scale gives the product of the formula in per cent.

Fig. 1.

A scale for the maximum clearance has been worked out on the same principle. For instance:

$$U = 20,000, B = 1,000, \text{urine per hour } 70 \text{ c.c.}$$

A line from 20,000 to 1,000 crosses U/B at 20. Connect 20 with 70 (cubic centimeters per hour). This line intersects the standard clearance scale at 40; that is, the standard clearance is 40 per cent.

In our medical ward the nomogram has been in use for nearly a year and has proved to be efficient and very simple.

A NOTE ON THE USE OF HENGAR SELENIZED GRANULES IN THE DIGESTION PROCEDURE FOR THE MICROGASOMETRIC DETERMINATION OF NITROGEN*

EDGAR J. POTH, PH.D., M.D., AND GEORGE A. ELLIOTT, B.A.
BALTIMORE, MD.

THE use of potassium persulfate as catalyst and oxidizing agent in the digestion mixture as recommended by Wong,¹ and adapted by Peters and Van Slyke,² fails to give consistent results. The destruction of the excess persulfate by the repeated addition of water to the digest cannot be effected uniformly. As a result the oxygen liberated by the reaction of the hypobromite and the residual persulfate in the gas chamber of the Van Slyke-Neill apparatus gives high values. The excess persulfate can be completely destroyed by the addition of oxalic acid, but this is a complicating and time-consuming procedure.

The use of a single Hengar selenized granule in 2 c.c. of a mixture consisting of three volumes of sulfuric acid (sp. gr. 1.84) and one volume of phosphoric acid (sp. gr. 1.71) insures complete digestion in ten to fifteen minutes. Not only is the oxidation catalyzed by the selenium, but bumping is eliminated by the porous granule. This digest is neutralized and treated with hypobromite in the manometric apparatus, as outlined by Peters and Van Slyke,³ with results which check in duplicate, as indicated in Table I.

TABLE I*
NITROGEN CONTENT OF PLASMA

SAMPLE	VOLUME TAKEN	MG. NITROGEN PER C.C.
1	0.1 c.c.	11.88, 11.80
2	0.1 c.c.	12.06, 12.22
3	0.1 c.c.	12.28, 12.10
4	0.1 c.c.	12.03, 12.08
5	0.1 c.c.	11.58, 11.51

*The results given here are duplicate values on consecutive samples taken in routine experiments.

By this procedure quantities of nitrogen from 0.5 to 1.5 mg. can be determined with an expected accuracy of one-half of 1 per cent. The blank corrections are consistently low.

SUMMARY

A modified procedure is presented for the preparation of the digest in the microgasometric determination of nitrogen.

A MODIFICATION OF THE PUCHER-SHERMAN-VICKERY METHOD FOR THE DETERMINATION OF CITRIC ACID*

BERTIL JOSEPHSON AND ULLA FORSSBERG
STOCKHOLM, SWEDEN

THE concentration of citric acid in blood or serum has been a subject of much interest since Sjöström¹ found that this concentration was increased in cases of injuries of the parenchyma of the liver. According to the experience of this laboratory, the test is one of the best laboratory methods for the differentiation of catarrhal jaundice (acute hepatitis) and icterus due to obstruction of the bile ducts. The test does not seem to be so sensitive as the hippuric acid test, though it is perhaps more specific than the latter.

Sjöström and several later investigators used Thunberg's method. In this method the citric acid decolorizes the dye methylene blue by means of an enzyme, citric acid dehydrogenase, from cucumber seeds. The concentration is calculated from the time needed for a certain amount of the serum to decolorize a certain amount of the dye. The method is rather time-consuming, and the decolorization times are not easy to establish with accuracy.

The chemical citric acid method by Pucher, Sherman, and Vickery² (the penta-bromacetone method) thus represented a definite advantage. In this method the citric acid is turned to pentabromoacetone, giving a yellow-brown color with sodium sulfide proportional to the amount of acid. The method has been much used in Sweden and other Scandinavian laboratories, and has proved to be satisfactory.

This method has, however, one drawback. The color developed is rather unstable and it fades in such short time that it can scarcely be used for colorimetry. For this reason, Pucher, Sherman, and Vickery mixed the final solution with pyridine to a concentration of about 40 per cent in order to stabilize the color. Using the method in routine clinical work, we have found that the pyridines from different factories give very different color strengths to the final solution of the same amount of acid. Even when the pyridine was distilled at a low temperature, its stabilizing ability soon grew weaker, and the color strength decreased. Only one of the tested pyridines did not change in this way. Moreover, the extinction coefficient of the pyridine mixture was not always directly proportional to the citric acid content of the solution. Sometimes a small amount of citric acid, 20 γ or less, did not give a higher extinction than the blank. Finally, the extinction coefficients plotted against the citric acid amounts did not form a straight line, as can be seen from the values of the

Received for publication, July 24 1941.

extinction coefficients divided by the amount of acid in Table I. On the other hand, the color once developed is very stable in pyridine solution (Table II).

TABLE I

Extinction coefficient (E) of varying concentrations of citric acid, and the proportion between this coefficient and the concentration (E/mg.). In the last column correction has been made for the amount of acid which did not give any visible reaction.

γ CITRIC ACID	GLYCEROL TWICE DISTILLED		PYRIDINE			
			REDISTILLED		PURISSIMUM	
	E	E/mg.	E	E/mg.	E	E/mg.
0	0		0		(-0.030)	
50	0.070	1.40	0.040	0.80	0.040	1.40
100	0.145	1.45	0.095	0.95	0.110	1.40
200	0.290	1.45	0.180	0.90	0.250	1.40
300	Too dark		0.360	1.20	0.390	1.40

In order to find a better color-stabilizing substance a great number of solvents have been tried as substitutes for the pyridine. The best one proved to be pure glycerol (*glycerinum bidestillatum*). When this solvent is used, the color is much stronger than that obtained with the best pyridine, and the extinction coefficient is directly proportional to the concentration of the acid (Table I). On the other hand, the color was not absolutely stable, and started slowly fading after two hours (Table II). This, however, is of no practical consequence. Glycerol of commercial quality may be used, but it gives a somewhat weaker color (Table II).

TABLE II

Extinction coefficient of the solution from 100 γ citric acid made up to 10 ml. read for different periods after the preparation.

MINUTES	GLYCEROL	PYRIDINE	
	TWICE DISTILLED	COMMERCIAL	REDISTILLED
0	0.150	0.130	0.095
60	0.150	0.130	0.095
120	0.150	0.130	0.095
240	0.145	0.120	0.095
300	0.130	0.110	0.095
390	0.120	0.100	0.095

Among the other substances tested, acetone and saturated sodium chloride solution had some stabilizing effect, but they were much inferior to glycerol.

In the experiments of which the results are given in the tables the penta-bromoacetone was extracted from its solution in petroleum ether three times, with 3, 2, and 1 ml., respectively, of sodium sulfide solution, according to Pucher, Sherman, and Vickery. The sulfide extracts were transferred to 10 ml. mottles containing 4 ml. of the stabilizing solvent. The solution was made up to volume with the same solvent and read with the light filter S:47 (which was found more convenient than S:43, the filter used by Pucher, Sherman, and Vickery).

AN AID IN THE DITHIZONE METHOD: A MECHANICAL SHAKER FOR SEPARATORY FUNNELS*

LAURENCE R. CRISP AND STEWART H. WEBSTER, PH.D.
BETHESDA, Md.

ONE of the most frequent operations in the determination of lead by the mixed-color dithizone method, as used in this laboratory,^{1, 2} is the shaking of the separatory funnels for the purpose of extracting various components from one phase or the other of the mixture. Although each shaking period is only a minute in length, this operation is repeated at least four additional times during the course of each determination. Experience has shown that in making thirty analyses during a day, more than three hours are consumed in shaking when this is done by hand. The tendency is to decrease either the speed or the intensity of shaking when the operator becomes tired.

Fig. 1.

In order to expedite the analyses and to obtain uniformly vigorous shaking a mechanical aid was devised (Fig. 1). This consists essentially of a maple rack to hold four 250 ml. Squibb type pyrex glass separatory funnels, this rack being given a reciprocating motion by means of an eccentric driven by a $\frac{1}{20}$ H.P. electric motor 1,725 r.p.m. The figure indicates the component parts of the device, with the rack removed to show details of the driving mechanism. The

Received for publication, July 29, 1941.

connecting rod crankpin is offset $\frac{9}{16}$ inch from center of eccentric, and the center-to-center length is $7\frac{1}{4}$ inches for the connecting rod and $6\frac{5}{8}$ inches for the four rocker arms. The heavy section of channel iron is bolted to a large box (18 by 28 by 20 inches high) filled with sand and mounted on No. 14 rubber stoppers to absorb the vibration.

The most difficult task is to hold the funnels securely, since they vary not only in length but also in the outside diameter of neck and stem as well as in length of neck and stopper. Of the several arrangements tried, the one described is the most satisfactory. Phosphor-bronze spring stock was bent to form clips as shown, so that after pushing the funnel down past the middle of the slot there is no tendency for the funnel to loosen up during shaking. The distance between the two slotted boards is slightly greater than the longest funnel in use. The spring holding the stopper in place has sufficient tension to prevent the stopper from coming out and allows for any differences in length of neck. By this arrangement no metal comes in contact with either funnel opening, thus avoiding contamination.

The funnels can be rapidly inserted and removed from the holders using only one hand. With pulleys 1 inch and 6 inches in diameter about 350 double oscillations are produced per minute. With an electric timing switch added, the minute occupied in shaking the four funnels can be used to carry out other operations. Two of these shakers, constructed in this laboratory, have given satisfactory service for over two years.

MEDICAL ILLUSTRATION

WATER COLOR DRAWINGS FOR SCREEN PROJECTION

FRANCES SHULTZ, BALTIMORE, MD.

HERETOFORE a transparent base has not been used extensively for hand-drawn pictures in color and tone. Such water color illustrations are made to serve as lantern slides primarily, but in the past color in flat washes or lines was used. Color also has been applied over photographs in tone, thereby producing the tonal effect. By experimenting over a period of six months, a method has been found for making a picture that is smooth enough to be projected on a sizable screen for lecture purposes. Of course, since color photography has taken such an important place in the illustrative field, the scope of the subject material for hand-colored lantern slides has been reduced. However, the hand-made slide still serves those items which cannot be photographed as clearly as they can be drawn, such as *peritoneoscopic*, *bronchoscopic*, and *cystoscopic* subjects.

When a transparent medium first was considered, several different materials presented themselves as surfaces upon which to work, for example, glass, cellophane, cellulose, film and other available transparent materials. I tried putting a clear varnish, similar to the one used by artists, on cellophane to keep it from wrinkling, but it became streaked when dry. It was then put on glass, but the same result was obtained. Ammonium hydroxide washed upon blue-tinted roentgenographic film and allowed to dry worked fairly well so far as shading of the different parts was concerned, but it changed some of the colors, for instance, blue became green.

About this time an article written by Dr. M. Muschat on "A New Technique in Medical Illustration" appeared in this JOURNAL. The article dealt with colored illustrations for lantern slides and was accompanied by a black-and-white print of a colored drawing by the author which did not seem to be smooth enough for projection. I was able to obtain some of the material he used, and on examination found it to be similar to other cellulose acetate and cellulose nitrate film, except that it had a ground surface on one side that was excellent to draw upon in pencil. When water colors were applied, however, they became slightly gray and could not be worked to a smooth finish. In short, the film was difficult to handle. Numerous experiments were made to determine which solution and which material would work together to produce this smooth finish. A bit of liquid glue in a small amount of water works well when applied to the film, but after this solution dries it cannot be softened sufficiently to scratch off the high lights without spoiling the film underneath. However, it is an aid in putting on a smooth tone and should not be discarded entirely.

The best method to use in making a smooth lantern slide is to prepare a solution of one part of gum arabic crystals to eight or ten parts of water. This may be thinned if desired. Paint the whole surface of a piece of blue-tinted roentgenographic film from which the gelatin surface has been removed by soaking it for a few minutes in warm water, and allowing it to dry. The water colors can then be used in the ordinary way. When the colors are dry and you are ready to scratch off the high lights, dampen the end of an etching tool which has been sharpened to a fine point and carefully scratch off the paint and the solution. The film itself will show through the solution and give the appearance of the highest high light. Insert the film upon which your drawing has been placed between two lantern slide cover glasses and bind with lantern slide binding tape. If you wish, you may make a mat of black opaque paper for the drawing and put it between the two cover glasses before they are bound.

Another medium upon which such colored drawings can be made is the cleared but unexposed and undeveloped lantern slide plate. For example, take a new lantern slide plate from the pack and place it in a photographic fixing bath. This bath clears the plate and leaves a piece of glass with a transparent film base. Such a base supplies the "tooth" to hold the water color pigments which should be applied in thin washes. It is the custom of medical illustrators to scratch or to engrave high lights out of their drawing base or surface rather than to apply white or light pigments with a brush. Because the lantern slide is a transparency, it is essential that the high lights be engraved out rather than built up. In applying the water colors to the surface as described here, the surface becomes damp and, therefore, unsuitable for engraving out the high lights until it is thoroughly dry. Once it is dry, it answers the purpose satisfactorily.

Many water-color pigments have an opaque base and are entirely unsuitable for the coloring of lantern slides and similar transparencies. For instance, the true earth pigments, such as yellow ochre and raw sienna, are particularly opaque and therefore unsuitable. All whites are opaque in varying degrees. For this reason, truly transparent colors should be used. These colors include some of the aniline dyes, which are invariably synthetic derivatives. Most of the dyes used in staining microscopic slides are of the transparent variety, but all of these do not lend themselves to the coloring of transparencies owing to their lack of permanence. The degree of permanence can be ascertained from a majority of the reputable manufacturers of colors. A fair degree of permanence is essential because the rays of light passing through a lantern slide are so great or intense at the point where the slide is placed in the machine that fugitive pigments will change rapidly. This change is caused by the light and heat intensity produced by the average projection bulb. The purchaser can do little more than rely on the word of the pigment manufacturer as to the permanence of his product. However, the transparency of a pigment can be tested by observing a small amount of it under a microscope with transmitted light. By this method the tiny particles of a pigment which appears to be of a definite color by reflected light become black or gray by transmitted

Tubo-ovarian abscess.

Tubercular lesion of the colon and abdominal wall.

These are typical examples of the method of illustration described in the text.

light. Genuine transparent pigments retain their color when studied by transmitted light. The artist must, therefore, choose a palette composed of transparent colors if he is to color lantern slides. Even if one opaque pigment gets mixed in with the rest of the palette a lack of transparency and brilliance will result. In art this is termed *muddiness* or *muddy color*.

A set of transparent water colors may be bought from most art and photographic supply houses in book or liquid form. These serve well for the purpose.

As a rule, it is best to dampen the working surface before the colors are applied. A pencil sketch on paper may be placed beneath the transparent material to serve as a guide in applying the color.

It must be remembered that any flaw, particularly a dark one, will show up when the slide is projected. Therefore, it is advisable to make the picture with great care. I use a stamp collector's magnifying glass, which has a swivel neck and a stand, through which to work. It aids materially in making such illustrations.

DEPARTMENT OF ABSTRACTS AND REVIEWS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

TUBERCLE BACILLI, Detection of, by Fluorescence Microscopy, Bogen, E. *Am. Rev. Tuberc.* 44: 267, 1941.

Sputum or other material, preferably after concentration, is thinly smeared on a glass slide. The slides may then be stained with any acid-fast staining technique, except that the carbolfuchsin is replaced by auramine. The staining solution is made by placing 1 Gm. of pure auramine powder in a flask, gradually adding 1,000 c.c. of distilled water, shaking strongly until it is completely dissolved, and then adding 50 c.c. of pure, liquefied phenol, and again shaking. A temporary clouding later settles out, leaving a clear yellow solution which keeps for a long time in the dark. Hagemann recommends staining with auramine for fifteen minutes at room temperature, and decolorizing with acid alcohol without counter-staining.

The following procedure, after Herrmann, has been used at the Olive View Sanatorium:

1. Fix with heat.
2. Flood with auramine solution, and steam for five minutes.
3. Wash in running water.
4. Decolorize in 70 per cent alcohol, containing 3 per cent hydrochloric acid, until the preparation is colorless.
5. Wash in running water.
6. Dip in a 0.1 per cent aqueous solution of potassium permanganate (this solution remains usable for about a week after turning brown).
7. Wash in running water.
8. Dip in Löffler's alkaline methylene blue solution.
9. Wash in running water.
10. Dry and examine with the fluorescence microscope.

Fluorescence microscopy is a new method for detecting tubercle bacilli. Its theoretical basis suggests advantages over the present microscopic procedures, both in speed and delicacy. An intense violet or ultraviolet source of radiation is required. The bacilli are stained with the fluorescent dye, auramine, and examined with an ordinary microscope equipped with special light filters. Practical experience confirms its predicted value. In 1,000 duplicate smears stained in parallel by the Ziehl-Neelsen and fluorescence methods, there were over 20 per cent more positive tests by the newer technique. In 250 parallel cultural and fluorescence microscopic examinations, the specificity of the latter was confirmed, although the cultural methods still gave considerably more positive findings.

JAUNDICE, Significance of Rise of Non Protein Nitrogen in, Meyer, K. A., Popper, H., and Steigmann, F. *J. A. M. A.* 117: 847, 1941.

The nonprotein nitrogen of the blood is increased in patients with both medical and surgical jaundice of severe involvement. The increase is more pronounced in cases in which there is a fatal outcome.

The determination of the nonprotein nitrogen is of diagnostic, and especially prognostic, value in such cases, since it points to an aggravation of a parenchymatous jaundice and to the appearance of a secondary liver damage in cases of obstructive jaundice. Increase of nonprotein nitrogen in a case of surgical jaundice suggests an early operative intervention.

The increased nonprotein nitrogen is to some extent explained on the basis of a reduction of glomerular filtration, but to a greater extent is due to increased reabsorption of urea in the kidney tubules.

An increased breakdown of protein as a cause of the increased nonprotein nitrogen is not evident from the authors' experiments.

BACTERIOLOGICAL TECHNIC: Improved Method of Obtaining Bacteriological Specimens From Wounds Treated by the Closed Plaster Method, DeWaal, H. L. Brit. M. J., Aug. 23, p. 268, 1941.

After the wound has been cleaned, sterile thick absorbent thread is laid backward and forward across its surface, starting at the center and passing to the periphery. The free end of the thread lies away from the wound. The whole of the wound surface is now covered with sterile vaseline gauze. The free end of the thread is passed through a "one-piece" vulcanite cylinder with a flat base and with the sharp edges smoothed off. (The vulcanite should be of good quality and able to resist autoclaving.) A groove is cut in the flat base of the cylinder in which the thread lies. This allows for the subsequent easy withdrawal of the thread. A sterile rubber stopper is inserted into the upper opening of the cylinder. While the plaster is being applied, an assistant steadies the cylinder at the edge of the vaselined gauze (about 1.5 cm. from the wound margin). In taking specimens the procedure adopted is as follows:

The rubber stopper is first removed, and with a swab slightly moistened in antiseptic the inside of the cylinder is cleaned and then dried with another swab. That portion of thread which had been within the cylinder and had come in contact with the antiseptic is now withdrawn, cut off, and discarded. A further piece of the thread is pulled out (about 1.5 cm.), snapped off, and placed in a sterile test tube. This portion of the thread has been exposed to air, and should be examined as a control. The next few centimeters are similarly collected, and give a representative sample of the wound flora.

Depending on the length of the thread originally laid on the wound, five or more specimens may be taken at varying intervals. The last portion of the thread comes from the center of the wound, the part likely to heal last. After each specimen is taken, a fresh sterile rubber stopper is inserted in the mouth of the cylinder.

LYMPHOCYTOSIS, Infectious, Smith, C. H. Am. J. Dis. Child. 62: 231, 1941.

Two types of lymphocytic blood reactions are described to which the term infectious lymphocytosis has been applied.

In one type, which occurs infrequently, unexpected hyperleucocytosis with absolute and relative lymphocytosis appears for a short period and is not accompanied by any recognizable symptoms or physical signs. In the two cases of this type reported in this paper the maximum white blood cell counts were 44,300 and 98,000 cells per cubic millimeter, respectively.

The second type is frequently encountered in pediatric practice and includes cases in which after an infection of the upper respiratory tract low-grade fever continues to be present for prolonged periods. Associated symptoms include anorexia, pallor, fatigability, and para-umbilical pain. The blood in such cases shows a lymphocytic preponderance instead of the expected neutrophilic response and moderate leucocytosis. This symptom complex occurs most characteristically in infants and in young children.

Examination of bone marrow in three cases showed an increase in lymphocytes as the only abnormality.

These two types are classified as acute and chronic infectious lymphocytosis, respectively, and are differentiated clinically, hematologically, and serologically from infectious mononucleosis, leucemia, and miscellaneous infections associated with lymphocytosis.

It is pointed out that many lymphocytic blood responses in children whose titer of heterophilic antibody is normal belong in the class of infectious lymphocytosis rather than infectious mononucleosis.

Acute and chronic infectious lymphocytosis may represent separate entities, although there is some evidence that they may be related.

The etiologic agent of each type is probably not represented by the bacterial flora obtained from the nasopharynx, but probably is an as yet undetermined virus related to infection of the upper respiratory tract.

The prognosis in both types of infectious lymphocytosis is favorable. Treatment of the chronic type is symptomatic and should be directed toward relieving nasopharyngeal infection.

CHICKENPOX, The Blood Picture in, Holbrook, A. A. Arch. Int. Med. 68: 294, 1941.

This study was made during an epidemic of chickenpox in Milwaukee County in the fall of 1939. The 56 patients and 15 controls were all quarantined in their homes.

The following significant tendencies are noted in the patients:

1. The total white blood cell count falls during the end of the incubation period, reaches the lowest level on the second and third days of the rash, and then rises to its former level.
2. During the leucopenia the percentage of polymorphonuclear cells falls, and the percentage of lymphocytes rises, as lymphoblasts and prolymphocytes come into prominence. Among the latter, the mitotic figures, which are occasionally seen, attest further to the strong stimulus to lymphocytic activity which apparently accompanies chickenpox.
3. An increase in plasma cells is also noteworthy early in the eruption stage, their portion of the total differential count sometimes reaching 6 to 8 per cent.
4. In some instances, several of the foregoing features may appear before the rash and thus may be of diagnostic value.

The studies on the control group show the following tendencies:

1. In the aggregate, the various plotted curves for total white blood cell counts and their fractions tend toward a horizontal line.
2. In certain individual cases, a fall in the percentage of polymorphonuclear cells and a rise in the percentage of lymphocytes, with prolymphocytes increasing, occur at about the time the eruption is expected.

VITAMIN C and Serum Protein Levels in Wound Disruption, Hartzell, J. B., Winfield, J. M., and Irvin, J. L. J. A. M. A. 116: 669, 1941.

The authors would emphasize Mason's statement that "the urge to heal is almost as great as the urge to live." Wound healing is affected by many factors, and the nutritional condition of a patient is a most important one. Either to maintain life or to repair tissue there must be a supply of proteins, fats, carbohydrates, minerals, water, and vitamins. Periods of inanition or faulty nutrition are likely to deplete the carbohydrates and fat stores and to lower serum protein and vitamin levels. The authors almost universally supply carbohydrate and salts by routine intravenous administrations, but, generally speaking, if a transfusion is given, it is because the hemoglobin and the red blood cell count are low rather than because the serum protein is low, and the vitamins are forgotten entirely. It would seem logical that, if normal healing is to be expected, the ascorbic acid and serum protein levels of the blood plasma should be brought to normal concentration and kept there.

MENINGOCOCCI AND GONOCOCCI, Simple Method for the Isolation and Identification of, Boisvert, P. L., and Fousek, M. D. Am. J. Dis. Child. 61: 710, 1941.

Twenty-six strains of meningococci and 8 strains of gonococci were isolated in the pediatric laboratory during a three-year period; the carbon dioxide jar of Thompson was used for the cultures. The organisms grew out well in twenty-four hours on blood agar plates and were recovered from material from all infected patients on the first culture. It was found that the simple addition of the differentiating carbohydrates to the blood agar afforded a satisfactory method for further identification of the organisms by fermentation tests.

Media.—A fresh beef heart infusion with 1 per cent neopeptone was the basic medium used. The blood agar plates used for the isolation of the organisms were made by adding 10 c.c. of defibrinated rabbit's blood to a flask containing 200 c.c. of melted infusion agar. The blood and agar were mixed, and the mixture was poured into sterile Petri dishes and allowed to solidify. The contents of one flask made about fifteen blood agar plates.

For the fermentation tests blood agar plates containing dextrose, maltose, and levulose were used. Five-tenths cubic centimeter of defibrinated rabbit's blood was added to a tube containing 10 c.c. of melted infusion agar. The contents of the tube were mixed and

poured into a sterile Petri dish containing 2 c.c. of 10 per cent dextrose. An even distribution of blood agar and carbohydrate was obtained by gently tilting the dish back and forth while the contents were still liquid. Blood agar plates with maltose and levulose were made in the same manner.

Carbon Dioxide Jar.—The apparatus consisted of a round, flat-bottomed 2.5 liter pyrex jar, a square cover with corked aperture, and a container for reagents. It differed only in minor details from the apparatus used by Thompson. The container for reagents was fastened to the bottom of the jar with sealing wax. Petrolatum was used to seal the cover to the jar.

Sodium bicarbonate and sulfuric acid were the reagents used. The sodium bicarbonate solution was made by dissolving 84 Gm. of sodium bicarbonate in 1 liter of water. The sulfuric acid solution contained 20 c.c. of concentrated sulfuric acid per 580 c.c. of water. Equal amounts of each reagent were used, and 22.4 c.c. of carbon dioxide were formed from each 1 c.c. of sodium bicarbonate solution. An amount of each solution, equal to 0.45 per cent of the volume of the jar, furnished an atmosphere of about 10 per cent carbon dioxide.

Isolation of Strains.—Purulent discharge from the eyes or the genital tract was obtained on a sterile cotton-tipped wooden applicator. It was smeared over a small area near the edge of a blood agar plate and streaked with a platinum loop.

A 0.1 c.c. sample of spinal fluid was placed on a blood agar plate with a sterile pipette and streaked in a similar manner.

Blood cultures were made by adding 5 to 7 c.c. of the patient's blood to 50 c.c. of infusion broth and by mixing 2 c.c. of the citrated blood of the patient with 10 c.c. of infusion agar to form a pour plate.

Material for culture was obtained from the nose by introducing a cotton-tipped wooden applicator into the nostrils until the nasopharyngeal wall was reached; material from the throat was secured by touching both tonsils and the posterior portion of the pharynx. The material from the nose and that from the throat were streaked separately on blood agar plates.

The inoculated media were put into the carbon dioxide jar, the calculated amount of sodium bicarbonate solution was placed in the container for reagents, and the jar was covered. An amount of sulfuric acid equal to that of the sodium bicarbonate solution was added through the hole in the cover by means of a pipette. The hole was closed with a cork, and the jar with its contents was incubated overnight at 37.5° C. Portions of colonies on the plates which resembled meningococci or gonococci were smeared on a glass slide, stained, and examined microscopically. Blood cultures positive for these organisms were examined in a similar manner. If gram-negative diplococci were found, the organisms were further identified by their fermentation reactions.

Fermentation Tests.—Three blood agar plates, containing dextrose, maltose, and levulose, respectively, were inoculated and incubated overnight in the carbon dioxide jar. One drop of 2 per cent bromthymol blue was placed on each of the plates in an area where colonies were present. Fermentation of the sugar was indicated by a change in the color of the indicator from dark blue to yellow.

BLOOD SERUM, Desiccated, Viability of the Spirochetes of Syphilis and Yaws in, Turner, T. B., Bauer, J. H., and Kluth, F. C. Am. J. Med. Sc. 202: 416, 1941.

T. pallidum and probably *T. pertenue* are commonly killed by the process of freezing and desiccation, even when the method is such that the viability of many other bacteria and viruses is retained. Transfusion of desiccated blood serum or plasma is, therefore, probably without risk as regards the transmission of syphilis or yaws, even though the material is obtained from an infected donor.

REVIEWS

Books and Monographs for Review should be sent direct to the Editor,
Dr. Warren T. Vaughan, 201 West Franklin Street, Richmond, Va.

Genital Functions and Their Hormonal Regulation*

INTERNATIONALLY known for his work in endocrinology, Dr. Zondek in this monograph presents and discusses the results of investigations carried on in the Hebrew University and the University Hospital in Jerusalem.

In six main sections are discussed: I. The Occurrence of Some Estrogenic Substances in Nature; II. Experimental and Clinical Investigations of the Percutaneous Use of Estrogenic and Androgenic Hormones; III. The Effect of Protracted Treatment With High Doses of Estrogenic Hormone; IV. On the Fate of Estrogenic Hormones in the Organism; V. Clinical Investigations Concerning the Cycle of the Female Organism; VI. The Mechanism of Menstruation.

Of interest is the report in the opening section of the demonstration of estrogenic hormone and a flavin derivative (vitamin B₂) in the water and sandy slime of the Dead Sea.

In Section III Dr. Zondek reports absence of any evidence that protracted hormone therapy may be, as has been suggested, a factor in carcinogenesis.

Space does not permit any extended résumé, but it can be said that these studies are of great interest and value to the investigator in this field and to the clinician as well because of their clinical aspects.

Well printed and excellently illustrated, this is a valuable contribution. A summary completes each chapter and a bibliography is appended.

Essentials of Endocrinology†

AS THE author comments in his preface, the field of endocrinology is marked at the present time by "feverish activity." His book, therefore, will be welcomed by those who wish to have at least a bird's-eye view of what has now become, in many respects, a fundamental science.

In this book Dr. Grollman presents a well-balanced survey of the present status of endocrinology and discusses in seriatim: Endocrine Glands of the Cranial Cavity; The Bronchiogenic Organs; Endocrine Glands of the Abdominal Cavity; Hormones of the Reproductive System; and The Hormones Derived From the Nonendocrine Glands.

A useful reference list of available endocrine products is found on the cover pages, front and back.

Well oriented and organized, well written and illustrated, this is a useful book deserving of wide circulation.

*Clinical and Experimental Investigations on the Genital Function and Their Hormonal Regulation. By Bernhard Zondek. Cloth, 264 pages, 59 figures, \$4.50. Williams & Wilkins Co., Baltimore, Md.

†Essentials of Endocrinology. By Arthur Grollman, Ph.D., M.D., Associate Professor of Pharmacology and Experimental Therapeutics, Johns Hopkins University, Medical School. Cloth, 480 pages, 74 illustrations, \$6.00. J. B. Lippincott Co., Philadelphia.

PROGRESS

SOCIAL REVOLUTION AND THE PHYSICIAN*

WARREN T. VAUGHAN, M.S., M.D., RICHMOND, VA.

LET us for a moment turn the calendar back eight short years, to the year of our Lord 1933.

This was a year of depression. The banks took a holiday. Even so, we were making progress. The eighteenth amendment was repealed, destroying the problem of racketeers. The Industrial Recovery Act was passed, assuring prosperity. The bonus grab was consummated, distributing billions of dollars, that our country might lift itself by its bootstraps. Chicago was celebrating a Century of Progress. Wiley Post was circling the world in eight days. The Golden Gate Bridge was abuilding and the first streamliner train was entering service. Science and medicine were making strides. Heavy water was being discovered; magic eyes were opening doors. Surgeons were removing entire lungs. The Rockefeller Foundation was spending fifteen million dollars to promote the well-being of mankind.

All was reasonably well with the world.

On January 30 a fiery little fanatic, Adolf Hitler, became Chancellor of Germany. Within the year Mower wrote a book, *The Brown Book of the Hitler Terror*. Armstrong wrote another, *Germany Puts the Clock Back*. The Nobel Peace Award for 1933 was postponed.

Will that year go down as the nineteen hundred thirty-third from the birth of Christ? Or will it gain more lasting place as the year "One" of the New Dark Ages?

There have been glorious epochs in history. A high point was the Age of Pericles, when commerce and industry, art, philosophy, and the science of the

*Convocation address at the opening of the University of Michigan Medical School, October 4, 1941.

time flourished. We read of the rulers and sages of that age, and call it Golden. We forget that its average persons lived as crudely as the barbarians who later destroyed them. We forget that the glories of ancient Greece were built upon a foundation of slavery.

If I had my choice of any half century in which to live during the last fifty thousand years, I would select the years just elapsed and would request life in a democracy, preferably in the United States. At no other time or place in the history of creation have men, from the wealthiest and the most intelligent to the poorest and the least intelligent, enjoyed comparable comfort and freedom.

True, this period has witnessed disease and crime. Utopia is not yet here, but it seemed almost within reach. At what point on the road of progress did our race stray into the bypath which has led us to the brink of disaster?

During the first World War a new element entered those factors which appeared to be controlling progress. A few recognized this at the time. Many do so now when it is almost too late. This new element is complex. It is a trend, best analyzed in the changes in social psychology since the last war.

In the intervening decades there has been continuous advance in the physical or mechanical aspects of living. Automobiles and ships have improved. Diesel trains, air-conditioned buildings, and other inventions have made living almost too comfortable. Scientific achievement is gaining, not losing, momentum. New discoveries are now heralded daily, and the science and the art of medicine are at a high point of achievement.

In these aspects the world appears to have been traveling onward toward grander things. The downward change has been in our attitude toward life, in our interpretation of the reason for existence, and in our evaluation of those things for which life is worth the living. I might say that in a mechanized world, our philosophy has become mechanistic.

Many factors have played a part. The first, a direct outcome of World War I, was man's unconscious denial of the value of human life. Only by the adoption of such an attitude can soldiers live through a war of destruction without going insane. When one sees dear friends, stalwart young men, blown to fragments, knowing that the next shell may be his own, one forgets the platitudes of the Sunday-school teacher on God's interest in the weakest lamb of the flock. The success of wars depends upon mass training in the psychology of the unimportance of the individual. All of us who were in France absorbed it, whether we were fighting with bayonets or merely closing the eyes of others as they died from violence or disease.

Such a psychologic attitude persists after its need has passed.

A second factor which in this country has changed the outlook of the masses was prohibition, which made gentlemen out of drunkards and drunkards of gentlemen; which allowed honest men to deal with crooks; which made connivers of policemen and bars into speakeasies; and which bred contempt of the law in every class, but most regrettably in children, as they watched their parents flout it and laugh.

I find a third conditioning influence in the present trend toward mediocrity in productive effort, especially among the laboring groups. Time was when craftsmen and their apprentices derived as much satisfaction from the making of an artistic copy of a famous statue, painting, saddle, nutcracker, or bookmark as the artist had in his original creation. Today, the trade unions discourage originality. All must be stereotyped. No matter what the degree of one's ability, all must work the same hours and receive the same pay. Creative ambition among craftsmen is discouraged. Once there were cabinet makers. Then there were carpenters. Now there are saw-and-hatchet men who piece together jigsaw puzzles of prefabricated materials.

These three influences, mediocrity, lawlessness, and negation of the importance of the individual, have probably been the most important factors in this country. The trend has been world wide. It is illustrated in the communism of Russia and the corrupt politics of France.

There is a fourth factor which has influenced nations. While Germany has been the leader in this factor, it has been reflected in her allies, Japan, Italy, and the Russia of 1940. It may be summarized in the term national dishonesty. If a government lies, cheats, steals, and murders, the ethics of those living under it must of necessity undergo subtle changes.

We are living in a period of world revolution, of turmoil, in which the socialistic trend, the trend toward mediocrity, the tendency to draw the best down toward the worst is dominant. We have seen civilizations fall. Is today's situation comparable to the softening that caused the downfall of Rome? Are we witnessing a temporary eclipse of civilization?

For myself, the answer is no. But I must qualify this answer.

We are entering a new world order, one which may not make the world better. We are in a phase comparable to the French Revolution. It involves a reshuffling in which the "haves" will become "have nots," but the "have nots" will not become "haves." The outstanding phenomenon of the catastrophe is the destruction of individualism. Individualism was destroyed in the French Revolution, but it returned. It will always return.

How have we managed to get ourselves into this predicament? Have we taken a byway off the path of progress? Or have we reached a previously uncharted area on the main road? Are there more basic conditioning elements than the superficially obvious ones which I have described? I see three such possibilities.

The first is the influence of cosmic forces. The suggestion has been made that those solar convulsions which cause sun spots may extend their influence to things living on earth. It has been shown that periods of social unrest coincide fairly well with phases of increase in sun spots. This applies to the World War, the Russian Revolution, and even to runs on the stock market. When William Petersen is showing how terrestrial weather may influence man physically, mentally, and emotionally, we need not stretch imagination to grant the possibility that cosmic rays or other solar forces might influence our activities. When C. A. Mills tells us that the upward trend in college student stature appears to be undergoing a reversal, and that sexual maturity is occurring at

a later age; when he attributes this to the unseasonable warmth prevailing over the earth since 1929; and when he remarks that the physical recession of mankind during the Dark Ages occurred during centuries of world warmth, we must ponder on the possible influence of cosmic forces on human progress.

We turn from such conjectures, since their acceptance implies a defeatist attitude. But we cannot ignore them if they may be true. If we grant their possibility, then our every effort should be to counteract such deterministic tendencies with whatever means science may make available.

We must consider human factors as well as geoastral forces. There are two: the growth of science, and the failing influence of religion.

The Christian religion has been the greatest social force for good that the world has ever known. I say this with full realization of the hypocrisy, injustice, corruption, torture, and brigandage that have been committed in the name of Christ. The Jewish, Buddhist, and Confucian religions have been comparably potent for good, although probably less widely effective. A single discovery nearly 400 years ago blasted the tenets of all theologies. When Copernicus proved that the earth revolves about the sun, our planet could no longer be the center of the universe. It became just a little ball, gyrating in unison with countless other little balls.

Men of science have been forced by their discoveries to become agnostic. They find no proof of individual life hereafter. They have adjusted themselves to the philosophy of contributing greatest good for the greatest number on this earth, and to the knowledge of immortality at least in the germ plasm of one's descendants. Surely we can speak of the religion of science. Members of this cult are today leading a more ethical life than are some so-called pillars of the church, even though the former have no fear of eternal damnation or hope of reward in the hereafter. In this way, the advanced thinkers have solved their problem. The trouble is that, with the popularization of science, nonthinkers have also become convinced that there is no hereafter. The great controlling force of orthodox religion over men with antisocial tendencies has been the fear of hell fire. With this gone, potential criminals are all out for what they can get in this life. Destruction of the concept of immortality, brought about by science, has been a potent factor in increasing crime on this earth.

We are living in days of realism. This applies even in the young. A five-year-old Jewish boy had heard his parents discuss the tragedy of the Jews in Germany. One day, disobeying injunctions, he went to the river bank where, of course, he fell in. His Mother told him that God, angry at his disobedience, had punished him. Next time God might let him drown. To which the lad replied, "I hate God." His reasoning was logical: "Why should God do that to me, when he does nothing to Hitler?"

The deity myth is one of the most remarkable phenomena in history. Anthropomorphic God failed his only Son two thousand years ago. Did we accept this as evidence of nonexistence? No, we made excuses, we explained that he wanted Christ to suffer like man. And this man-made illusion has continued

to govern the world for two millennia, fortunately so, because we were not ready for the next step in human evolution.

It has been said that the one hope for dogmatic religion is the arrival of a new Messiah. He must come from the lowest classes. He must fire the imagination. His religion must be militant. It must offer promise of heaven on earth. Today some see such a Messiah. His name is Adolf Hitler. He is the most evil genius that the forces of creation have ever let loose upon this earth.

What may we expect from science? Scientists have realized that average man must have a tangible religion. To this extent they have regretted the passing of the old. Some have attempted to substitute a religion of ethics based upon science. Their writings usually start convincingly and end in a philosophic hodgepodge which leaves their readers and, I suspect, themselves in a complete fog, proving that the scientist should limit himself to science and leave metaphysics and philosophic dissertations to those better qualified in the field.

One writer, Edwin Conklin, has avoided the pitfalls. In his essay "Does Science Afford a Basis for Ethics?" he formulates the answer more clearly than any other whose writings it has been my pleasure to read. Briefly excerpted, his reasoning is as follows.

"There is evidence that in times long past there were types of human beings, more brutish in body, mind and social relations than the general average of the present race. There is abundant evidence that ethics has undergone evolution no less than intelligence. It seems incredible that reason, emotion, aspiration and ethics should develop out of such simple functions as sensitivity, reflexes, trial and error, and yet these incredible things are actual facts.

"Psychical development begins with the ability to respond differently to stimuli of different quality or degree. Just as the amoeba avoids extremes of hot or cold, all living things grow toward the satisfactory and avoid the unsatisfactory. This is the beginning of psychic life. It is based upon the ability to distinguish between that which is satisfactory and that which is not, and to follow after the one and to avoid the other. This very fact of distinguishing and choosing or following is the basis of wisdom. Freedom comes with the ability to make a choice between two alternatives, and is measured by the extent to which remembered experience influences behavior. Intelligence is the capacity of profiting by remembered experiences.

"The highest level of human development is attained when purpose and freedom joined to social emotion, training and habits, shape behavior not only for personal but also for social satisfaction, since society no less than the individual is seeking satisfaction. When all these things combine, we have what we call ethics or the science of right conduct.

"The process of evolution involves not only the physical body but mental attributes and ethical reactions. Ethical or social reactions can be measured in groups of laboratory animals as easily as physical attributes. Evolution occurs in the body, the mind, and in social relations.

"Among savage tribes ethics or altruism pervades the tribe but does not extend beyond. In the higher social grades altruism reaches farther and takes in more people, until with some persons it includes the whole human race."

Cyril James has defined society as "an organism which we can envision as endowed with a kind of independent life that enables it to continue in existence despite the procession of births and deaths that determines the lives of the men and women who compose it."

We may gather several inferences from these statements. "Survival of the fittest" does not apply only to brute force. The prize fighter is not best fitted to fly a plane, to operate a submarine, or to organize an ideal social group. In evolution the highest men have developed not only physically and mentally but also socially or ethically.

The distinctive attribute of Jesus was that he was from 2,000 to 4,000 years ahead of his time. In the evolution of man, as far as ethics is concerned, he was precocious. There were others such as Moses and the Greek philosophers. With increasing numbers in later centuries, progressively fewer stand as far above their fellow men.

Socially, Christ was a perfect man. Plato was another, of almost comparable stature. His "Republic" is still the ideal to be attained, although it may be another two thousand years before we reach it.

There is another inference that I would draw from Conklin's essay. In the process of evolution among social organizations the democracy is farther advanced than any other form of government. The difficulty with the democracy of today is that, although it has a thousand superior ethical thinkers to one superior thinker of two thousand years ago, the mass of its members is not yet sufficiently evolved. When evolution has proceeded to that stage where all have acquired ideal ethics, then democracy will be perfect. I believe that time will come.

A corollary is that the Germanic tribes of today are not at as high a stage of evolution as the English, the Scandinavian, the American, and those other political communities which have demonstrated their capabilities for self-government. The German people have no genius for this. We blamed Wilhelm in 1914. We blame Hitler now. If there had been no Kaiser or no Hitler there would have been someone else. The trouble is with the mass psychology of the Teutonic race as much as it is with its rulers. The ethos, the code of ethics of the democratic states, is one of "give and take." The Nazi code is simply that of "take."

Our error at the last peace was the assumption that democratic government would be appropriate for men who were insufficiently evolved to handle it. If the democracies win this war a benevolent authoritarian government must be set up for Germany.

I find food for thought in the observation that while the Celts and then the Teutons first settled northern Europe, the Saxons and Angles broke away from the latter, to inhabit the British Isles. These could not tolerate a static life any more than their descendants who colonized America. Those who pushed always farther into the unknown where they could develop new and better social organizations may have been those farthest advanced in evolution. If we accept the cradle of the Aryan race as in Western Asia, and compare the Slavs, the

Teutons, and the Anglo-Saxons, we may conclude that the farther they have gone geographically the better has been their capacity for self-government.

I do not wish to imply that the democracies have a monopoly of the finest minds. There have been superior ethical men in Germany, also in the Slavic nations and elsewhere. Many in Germany have been Jews, but some have been Teutons. The fact remains that when the Mediterranean races were in the flower of civilization, the Germanic tribes were still barbarians. For all of Hitler's vaunting of his personal group of Aryans, and in spite of the many fine minds that have lived in Germany—and escaped from Germany—compared with the most highly evolved groups in the world today, those who rule Germany now are one thousand years behind. They are still in the period of rule by deceit, cunning, and might. Their social ethics has not yet matured.

When Hitler entered Poland he told his people that he had taken a step which would change the history of the world for a thousand years. If he wins, this will be true. Human progress will have to step back one thousand years, and hope that a thousand years hence it will be back where it now is. I say this advisedly. Hitler's policy is one of destruction of the thinkers, the progressives, the ethical. During the two thousand years since Christ we have reached that stage where there is an appreciable, almost a militant, proportion of ethical persons. With their destruction, the rule of the barbarian will be complete, and the clock will have been set back ten centuries.

What will this world be like a thousand years from now? Kirtley Mather tells us that the present supply of oil in the United States will be exhausted in thirty years; the known world's supply, within seventy-five years. We have enough coal to last two thousand to three thousand years. Science can now make gasoline and similar products from coal. But there will be an increasing demand for nonrenewable products, such as coal and metals. Mather estimates that the demand will be doubled within a few decades. There will also be an increase in population. He concludes, "Taking all these things into consideration it would appear that world stores of needed natural resources are adequate to supply a basis for the comfortable existence of every human being who is likely to dwell anywhere on the face of the earth for something like a thousand years."

May I, for the sake of rhetorical effect, stretch my imagination and ask you to stretch yours to visualize a Hitler victory which will set the world back a thousand years; which will result in colossal wastage of nonreplaceable resources as is occurring today in the sinking of ships, the destruction of property, and the wanton explosion of those things which should be used by superior man in his daily life, ending a thousand years from now in the bankruptcy of our resources and the extinction of the human race?

Mather tells us that species like the dinosaurs, which have become extinct, lived an average of half a million years before they vanished. *Homo sapiens* has had only fifty thousand years of existence. Must we let Hitler and his minions rob us of four hundred and fifty thousand years?

Thirty years ago Prussian scientists were boasting racial superiority. Today it is Aryan purity. Then, it was superman. The superman of today is less

common among the Germans than in the more socially integrated democracies. Arrogance, intolerance, and sadism are not his characteristics.

During the era of splendid German scientific achievement, around the turn of the century, they were so positive, so dogmatic, so intolerant of dissension that they convinced not only themselves but many others of their intellectual superiority. After several decades the clay feet commenced to show. I was amused recently by the writings of some leading Germans regarding the causes of hay fever and asthma. Their conclusions of 1900 were as wrong as they could be. Today we know that hay fever is not a bacterial infection, and that asthma is not primarily a neurosis, but if you were to read those forty-year-old essays today and were not acquainted with progress in the intervening period, you would be as convinced as they were of the infallibility of their conclusions.

No, superman will not be defined in terms of the physical or mental prowess of the individual, but rather in his adaptation as a unit in the social structure. Christian kindness, not arrogance, will be his outstanding characteristic. He will not hesitate to fight if necessary, but only for truth and justice. Even Jesus drove the money changers from the temple. I say *Christian* kindness because Christianity is still an ideal religion. Take away the concept of the supernatural which was added after Christ's death. Take away the promise of personal immortality. What have you left? We still have the keystone—the teachings of Christ—a creed of moral and social ethics which has no superior.

We still have the Golden Rule.

The Prussian's conceit almost convinced us that his was the race of supermen. We are startled to discover that with the rationalization of science we ourselves have better claim to this distinction. If this is true, we have a heavy obligation, the task of preserving the higher civilization from destruction by those less advanced races which have assumed a camouflaging veneer of culture and are now using the implements of science, devised for social progress, for destroying society.

Here are you young men and women, at the beginning of your life's career, full of enthusiasm and ambition, and the feeling that all is reasonably well with the world. And here am I, an apostle of semigloom, invited here to wish you Godspeed and success. By way of apology and explanation may I say to you that I have four sons, all headed for careers in medicine. As a father, world problems have given me deep concern. I can only say that the advice I am giving you is the advice that I have given my own sons.

There have been other purveyors of gloom. The man who said "there is scarcely anything around us but ruin and despair" was William Pitt, the date 1800. The Duke of Wellington on the eve of his death in 1851 "thanked God that he could be spared from seeing the consummation of ruin that was gathering around." Disraeli ten years earlier had written, "In industry, commerce and agriculture there is no hope." Lord Shaftesbury said in 1848, "Nothing can save the British Empire from shipwreck." A hundred and forty years ago Thomas Jefferson wrote that dictators will "destroy every trace of civilization in the world and force mankind back into a savage state."

Today it seems truer. It may be because of our proximity or because the social upheaval is more world wide. Undoubtedly the future will be different.

What are you young men and my sons and I and the rest of us to do about it? I can give you only the high points.

First, you must prepare yourselves. Some of you are about to finish your medical education, others are just beginning. There will be a shortage of doctors and you will aid in keeping this at a minimum.

Next, your function will be to help win the war, for I can assure you it is our war, a battle against extinction of the most highly developed groups of the human race. Once you are in it, war is not a horrible affair. It is a thrilling experience. Otherwise it would not have been so popular through the ages. There is a mass psychology which destroys the sense of fear. You may be killed; if so, you will not remember it. You may be maimed, and this is the sad part of war; in the present barbaric struggle this applies equally to noncombatants. The chances are better than even that you will come through unscathed. There will be hardships, possibly heartbreaks, but we who went through the last war know that these are speedily forgotten and that in retrospect, and indeed in the day-to-day experience, fighting is lots of fun.

After we have won the war or, God forbid, lost it, what then? Present trends presage increasing socialization, involving scientists and physicians with the rest of humanity.

May I present three general alternatives? First, you can attempt to change the trend, whatever it may be, in an effort to retain present-day customs. This had best be left to geniuses or fools.

Second, you can "play the game." If individualism is temporarily eclipsed in America, and preventive and therapeutic medicine are to be regimented along with public health administration, enter this new day with enthusiasm and a spirit of cooperation. If medicine must become bureaucratic, do your best to reach the top in the new order, where you can do your part in making state medicine the finest type of medicine. Do this with only one object in view, to uphold the spirit and tradition of the best in our profession, applying it to the new order. In this way will you achieve lasting and self-respecting success.

If, again God forbid, we return to the Dark Ages, your function should be that of preserving the advances made up to now, while awaiting the dawn of a new era. Your lives should then be comparable to those of the monks of the Middle Ages, the monasticism which kept knowledge alive, albeit feebly, until the new day. In short, the third alternative is that of cloistered existence in research and teaching in schools of higher education.

There is a fourth alternative. It has neither the spectacular appeal of the first, the active appeal of the second, nor the self-abnegation of the third. It is the program which will be followed by the rank and file of you, the life that has made medicine a glorious profession, and has made doctors beloved by their people. This consists in aiding the sick, advising the disturbed, encouraging the feeble, comforting the bereaved, building health and happiness for the individual, and letting the more ambitious worry about the first three alternatives.

Physicians are, on the whole, more highly evolved ethically than many other groups. Furthermore, the doctor is in less conflict with current politico-social trends than are others. The future will bring fewer basic changes in medicine than in other fields.

Each of us will find his function in one or another of these categories, and each will be doing his part to preserve the human race from deterioration. We are fortunate in that none of the schedules calls for wanton destruction of our fellow men, although this is mandatory for others, if humanity is to persevere. Nevertheless, we should be willing to fight, with arms if necessary, for that which we know to be best for the human race. Today, Hell hereafter disturbs us not at all. But Hell on earth is at our doorstep. Let us all become members of the new religion of science, the religion of moral and intellectual decency; a religion which is so jealous of human progress that it is willing to destroy ruthlessly all deterrents; a religion of ethics, whose decalogue may some day contain no prohibitions—no “Thou shalt nots”—but whose code of human relationships is summarized in the English phrase, “Is it cricket?”

It would seem appropriate in closing to read you a few words from an essay on “The Evolution of the Superman,” written many years ago by Dean Victor C. Vaughan, who was beloved by all who knew him during his forty years’ service with this School.

“Men are mortal but man is immortal. The individual lives are at best but a span, but the race continues. Numberless finites make up the infinite, and yet the soundness of the part determines the perfection of the whole.”

It rests, then, with us as individuals, each to do his part, great or small, in assuring to posterity the continued upward progress which ethical man has striven so laboriously to deserve.

CLINICAL AND EXPERIMENTAL

PHARMACOLOGY OF THYMOXYETHYLDIETHYLAMINE*

DAVID R. CLIMENKO, M.D., PH.D., EDMUND HOMBURGER, AND
FREDERICK H. MESSER, PH.D., RENSSELAER, N. Y.

THYMOXYETHYLDIETHYLAMINE is a phenolic ether with the following chemical structure:

The free base is an oil, insoluble in water. The readily formed hydrochloride dissolves in water, a 3 per cent solution having a pH 3.0. Such solutions are unstable, primarily because of photosensitivity of the compound; however, they may be kept intact for a period of months in sealed ampoules under nitrogen and stored in the dark.

This compound was first described by Anan¹ who called attention to its sympathicolytic properties resembling those of the ergot alkaloids. Asakura² showed that it could inhibit the appearance of the adrenalin-induced hyperglycemia in the intact animal. Bovet and Maderni³ showed that thymoxyethyldiethylamine, together with a number of other phenolic ethers, was capable of producing an ergotoxin-like reversal of the pressor effect of epinephrine on anesthetized dogs; this action they attributed to a paralysis of the sympathetic end plates. Levy and Ditz⁴ made a similar observation on thymoxyethyldiethylamine and a number of its substitution compounds, describing the action as similar to that of ergotoxin or yohimbine in its ability to cause a reversal of the usual epinephrine effects.

Okazaki^{5, 6} has given a detailed description of the pharmacologic properties of the methyl homologue of this compound, thymoxyethyldimethylamine. He points out that the compound has an effect as potent as that of ergotamine on the isolated rabbit uterus, that it is considerably less toxic than ergotamine (frogs), and that it is capable of causing a reversal of the typical adrenalin pressor effect. According to Staub,⁷ this compound is in use in Japan as a therapeutic agent under the name "Tostramin."

Another closely allied substance, the diethylamine ethyl ether of 2-methoxy-6-allyl-phenol, has been described by Eicholtz,⁸ and by Schmidt and

*From the Research Laboratories of the Winthrop Chemical Company, Inc., Rensselaer.
Received for publication, October 21, 1940.

Scholl,⁹ under the proprietary name "Gravitol," and has been used clinically as an oxytocic agent in the treatment of uterine inertia, etc.

Fourneau and his co-workers¹⁰⁻¹² pointed out that certain phenolic ethers, particularly thymoxyethyldiethylamine, have the capacity of counteracting the effects of histamine, both in vitro and in vivo. The typical histamine-induced contractions of isolated smooth muscle could be inhibited by the previous addition of this compound to the bath fluid, and guinea pigs could be protected from the parenteral administration of two lethal doses of histamine by the previous subcutaneous administration of doses of 40 mg. per kilogram of the thymol derivative. Similar doses could also save sensitized guinea pigs from lethal doses of horse serum which produced fatal anaphylactic shock in unprotected animals.¹³ This protection was achieved without influencing the sensitizing-desensitizing mechanism, for such animals behaved in the same way as controls when a subsequent precipitating dose of horse serum was administered some days after the administration of the thymoxyethyldiethylamine.

Fig. 1.—Loop of guinea pig jejunum in Webster's solution containing atropine. The normal response to the addition of 1% of histamine to the bath fluid, followed by a wash and the addition of 0.4 c.c. of a 0.01 per cent solution of thymoxyethyldiethylamine. The normal histamine response is only observed after 1% of histamine have been added. The preparation is washed, and the response to 1% of histamine is again obtained. The addition of 0.2 c.c. of thymoxyethyldiethylamine causes an immediate relaxation of the contraction inaugurated by the histamine, and another normal histamine response is evoked after the addition of 2% to the bath.

More recently, Rosenthal and Minard,¹⁴ and Lambert and Rosenthal,¹⁵ have described thymoxyethyldiethylamine as having a specific protective action against histamine and have used this observation to support their thesis that it is the local liberation of histamine which gives rise to the sensation of cutaneous pain. They have described thymoxyethyldiethylamine as possessing a local anesthetic action of about twice the potency of novocaine, but have failed to mention the intense local reactions resulting from the subcutaneous administration of this substance. We have repeatedly observed local edema, local necrosis, and sloughs following the subcutaneous administration of 1 per cent solutions. Staub has also called attention to this local effect and has pointed out that one drop of a 1 per cent solution will cause persistent congestion and lacrimation when placed on the rabbit's conjunctiva, and that urticarial papules may be produced when the material is passed through the skin by iontophoresis.

Staub has shown that thymoxyethyldiethylamine is capable of inhibiting the response of the isolated loop of guinea pig jejunum to doses of histamine

which would ordinarily induce maximal contractions. We have also observed this effect and have found that a quantitative relationship exists between the amount of histamine inhibited and the amount of thymoxyethyldiethylamine present. Thus, as illustrated in Fig. 1, doubling the amount of thymoxyethyldiethylamine added to the bath doubles the amount of histamine antagonized. Staub has shown that thymoxyethyldiethylamine not only inhibits the oxytocic effect of histamine but also causes almost complete inhibition of the normal response of acetylcholine and a suppression of the normal response to barium chloride. Rosenthal and Minard, however, claim that the antagonistic action of thymoxyethyldiethylamine for histamine is specific, and that small doses, capable of causing complete suppression of the isolated preparation's response

Fig. 2.—Loop of guinea pig jejunum in Webster's solution containing atropine. A maximal response is elicited by the addition of 1% of histamine to the bath. The addition of 0.1 c.c. of a 0.01 per cent solution of thymoxyethyldiethylamine causes immediate relaxation of the muscle. The preparation is washed, and a second contraction is initiated by the addition of 20 mg. of barium chloride. Relaxation occurs immediately when the same quantity of thymoxyethyldiethylamine is added to the bath.

to histamine, have little or no effect on the contractions resulting from the addition of barium chloride, acetylcholine, sodium sulfocyanide, potassium chloride, or tyramine to the bath fluid. Our results do not bear this out, but are in closer agreement with those of Staub. We have found that quantities of the thymol derivative which will cause suppression of histamine contractions of the isolated gut will also render that preparation incapable of responding to barium chloride, and that concentrations which will cause immediate relaxation of smooth muscle after histamine stimulation will have a similar effect on contractions resulting from the administration of barium chloride. This observation is not compatible with any claim for specific antihistamine action. Sufficiently high concentrations of most spasmolytic or narcotic agents will curtail or completely inhibit the responsiveness of smooth muscle to oxytocins. Katz¹⁶ has pointed out the fact that chloral hydrate, urethane, and ether will inhibit the response of smooth muscle to histamine. Downs and one of us (D. R. C.)¹⁷ have shown that dibromoethylene behaves similarly with respect to histamine and the ergot alkaloids, but does not inhibit the contractions in-

itated by the addition of pituitrin. This does not mean that these substances have a specific antihistamine effect, but rather that the muscle fibers are narcotized, or rendered incapable of responding to oxytocic stimuli. We are of the opinion that this is equally true of thymoxyethyldiethylamine.

Fig. 3.—Cat under sodium barbital anesthesia. Record of carotid blood pressure, gastric contractions, and respirations. Time in five-second intervals. The fall in the blood pressure and the contraction of the smooth muscle resulting from the administration of 0.5% of histamine per kilogram are first recorded. This is followed by the intravenous administration of thymoxyethyldiethylamine (5 mg. per kilogram) which causes the death of the animal.

The parenteral administration of thymoxyethyldiethylamine to intact animals gives rise to a number of dramatic effects. To begin with, the compound is quite toxic. Staub gives the toxicity in Table I. She points out that toxic

Guinea pig	200	20
Mouse	500	25
Rabbit	200	25

symptoms occur after the administration of doses as small as 10 per cent of the minimal lethal dose. We have observed fatal outcomes from the administration of doses as small as 1 mg. per kilogram intravenously to cats under sodium barbital anesthesia. The first effect is a slowing of the respiratory rhythm associated with a diminution in the amplitude of the respiratory movements. This is followed immediately by a precipitous fall in the blood pressure which is maintained at the shock level for about one minute. During this time apnea sets in. When the apnea has become complete, the heart fails and the blood pressure falls to zero.

It should be pointed out that the vasomotor system is rendered incapable of responding to potent stimulation during the time the blood pressure is at the shock level, for the administration of epinephrine in doses as large as 0.5 c.c. of a 1:10,000 dilution failed to evoke a significant response.

The intravenous lethal dose was determined for adult male rats, weighing between 350 and 400 Gm. The results, which are shown in Table II, are of the same order as those described by Staub.

TABLE II

NUMBER OF ANIMALS	DOSE (MG./KG.)	RESULTS

				Dyspnea and convulsions
10	18.0	2	8	As above
3	19.5	0	3-	As above

Subcutaneous toxicity was determined on mice, and here again our figures agree with those obtained by Staub. Doses as small as 25 mg. per kilogram, however, produced marked inflammatory reactions at the sites of injection. When the dose level was increased to 100 mg. per kilogram, the inflammatory reaction was intense; the skin and subcutaneous tissues first became erythematous and edematous, the skin underwent necrosis, and the involved tissues sloughed away. Table III shows the results of the subcutaneous administration of an aqueous solution (1 per cent) of thymoxyethyldiethylamine hydrochloride to mice.

Henry,¹⁸ working with Staub, attempted a clinical trial with this material, but found that man did not tolerate it. Within one and one-half hours after the oral administration of doses as small as 1.5 mg. patients complained of a sequence of disturbing side reactions. The voluntary muscles became stiff and sore, those muscles which had been fatigued by previous exercise being the first to be involved. This was followed by dyspnea and dysphagia, hyperesthesia of the skin, and lowered blood pressure. In one individual the dyspnea was

sufficiently marked to cause a feeling of suffocation of sufficient intensity as to give rise to considerable anxiety. In this patient the toxic reactions persisted for three hours. Increasing the dose caused an exacerbation of the symptoms previously described. When the level reached 20 mg., the muscle "stiffness" became acute muscular pain, the dyspnea was intensified, and nausea and vomiting occurred. The patients suffered from such intense headache that they were unable to maintain an erect posture.

Staub showed that guinea pigs may be protected from two lethal doses of parenterally administered histamine if a previous subcutaneous injection of 40 mg. per kilogram of thymoxyethyldiethylamine had been administered. We have been able to verify this observation.

Fig. 4.—Cat under sodium barbital anesthesia. Record of carotid blood pressure, gastric contractions, and respiration. Time in seconds and intervals. The fall in blood pressure and the contraction of the gram of histamine resulting from the subsequent administration of the same dose of histamine is not affected.

The thymol derivative has no effect on histamine in vitro; that is, it will not combine with histamine to produce an inactive compound, nor will it convert it to an inert form. This is demonstrated by the following experiment:

Fifty milligrams of thymoxyethyldiethylamine were added to 100 c.c. of a phosphate buffer solution at pH 7.4, containing 1 mg. of histamine monohydrochloride. This system was thoroughly oxygenated and incubated at 37° C. for twenty-four hours, during which time it was under continuous agitation. At the end of this time the solution produced characteristic vasomotor responses in the intact cat, which differed in no way from those evoked by the administration of an equal quantity of untreated histamine. Under the same conditions, one unit of histaminase (Torantil) will inactivate 1 mg. of histamine monohydrochloride.

When the compound is administered subcutaneously to the intact anesthetized animal, a number of reactions occur which are dependent on the size

of the dose. Doses up to 10 mg. per kilogram produce no apparent effect. There is a slight fall in the blood pressure, but there is no effect on the respiratory rate or rhythm. The lowering of the blood pressure by small doses of histamine is not altered by this order of dose.

Fig. 5.—Cat under sodium barbital anesthesia. Record of gastric contractions, carotid blood pressure, and respirations. Time in five-second intervals. The administration of 20 mg. per kilogram of thymoxyethyl diethylamine causes a profound loss of tonus in the smooth muscle of the gut. The vasomotor reaction to 1γ of histamine is markedly diminished, but not completely abolished.

Fig. 6.—Cat under sodium barbital anesthesia. Record of gastric contractions, carotid blood pressure, and respiration. Time in five-second intervals. The normal response to 1γ of histamine is first recorded. This is followed by the subcutaneous administration of thymoxyethyl diethylamine (30 mg. per kilogram) which causes a definite fall in the blood pressure. Within three minutes the effect of 1γ of histamine has been abolished. One hour later the administration of 0.1 c.c. of a 1:10,000 solution of epinephrine produced no significant elevation of the blood pressure. Two hours after the administration of the thymoxyethyl diethylamine, 10γ of histamine produced no significant fall in the blood pressure, and 0.2 c.c. of epinephrine caused no rise in the blood pressure.

Increasing the dose to 20 mg. per kilogram causes a more marked fall in the systemic blood pressure which is associated with a slight increase in the respiratory rate. The most prominent effect of doses of this order is the marked loss in tonus of the smooth muscle. At this time the reaction to standardized doses of histamine is markedly reduced, but not completely abolished.

If the dose of thymoxyethyl diethylamine is increased to 30 mg. per kilogram, the fall in the blood pressure is more marked and the effects of small doses

MENOPAUSE ARTHRALGIA*

WITH A PRELIMINARY REPORT ON THE USE OF STILBESTROL

WILLIAM K. ISHMAEL, M.D., OKLAHOMA CITY, OKLA.

THE diagnosis of menopause arthralgia could well be summed up as:

"A female, fat and forty-four
Who frowns from feverish knees,
She 'fans in church,' her arms are sore,
For hot flashes and flushes that freeze."

Seriously, this group of patients, whose symptoms are probably more annoying than pathologic in the early phase, do many times lead to a painful crippling condition of the weight-bearing joints later, as is borne out by histories obtained from older women who date their symptoms back to around the age of the meno-

*From the Bone and Joint Hospital, University of Oklahoma School of Medicine, Oklahoma City.
Received for publication, October 25, 1949.

pause. At the present time complete clinical remissions are expected in the average patient who has received the diagnosis of menopause arthralgia. Should one of these patients fail to respond to treatment, we are more apt to question our diagnosis than the efficacy of the present established treatment.

Although the syndrome of joint and muscle pain, which occasionally accompanies or follows the artificial or the natural menopause, has never been widely accepted as a definite pathologic entity, nor the mechanism by which it takes place clearly demonstrated, the results from treatment of this syndrome certainly warrant grouping this type of rheumatic disease for special treatment. Francis Hall,¹ in his monograph on menopause arthralgia, has most ably described this syndrome and reports gratifying results in treatment from the use of estrogenic materials. In discussing one of Hall's papers² on this subject, I^{3, 4} suggested the use of 10 c.c. of autohemotherapy reinforced with 101 degrees of artificial fever for one hour, together with the estrogenic materials in the treatment of those patients who fail to respond to the estrogenic materials alone. My results from the use of estrin compounds compare favorably to those reported by Dr. Hall.

PLAN OF TREATMENT

In the series reported here the following plan of management was applied to those carefully selected patients classed as menopause arthralgia:

A. General Supportive Measures:

1. Diet: Low carbohydrate, high vitamin on those patients who are overweight; otherwise a normal, well-balanced diet.
2. Avoidance of traumatic factors; this involves a myriad of things, such as general and local rest, proper shoes, avoidance of occupational strains, posture, etc.
3. Avoidance of climatic factors, such as cold, dampness, drafts, wet hands and feet, exposure, etc.
4. Foci of infections; these to be left intact throughout the active treatment or while rheumatic symptoms are present.
5. Supplementary vitamins; these to be used on patients who present a clinical deficiency. In this series the use of the vitamin B complex was most frequently indicated, especially in the group seen at the Arthritic Clinic at the Oklahoma University Hospital and the School of Medicine. Several of this group were diagnosed as having clinical pellagra.
6. Correction of disturbed or abnormal systems present, such as metabolism, gastrointestinal function, emotional stress, posture, and other pertinent factors affecting the patient's normal health.
7. Relief of pain.

B. "Specific" Measures:

1. In this phase the patients were divided into groups:
 - (1) Injectable estrogenic hormone used in 60 patients who received an average of 10,000 units twice weekly over an average period of from four to ten weeks.

- (2) Estrogenic hormone given by mouth or by insertion into the vagina. Thirty-four patients received 0.12 mg. in capsule form daily for an average period of four weeks.
- (3) Stilbestrol (dihydroxy alpha, beta diethylstilbene) by subcutaneous injections; 60 patients received an average dose of 0.25 mg. (7,500 international units) twice weekly for an average of from four to ten weeks.
- (4) Stilbestrol by mouth: 30 patients received 1 mg. in tablet form averaging from every two to four days.
- (5) Autohemotherapy: As mentioned, this measure was supplemented only in those patients in whom the pathology had reached an advanced degree or who had failed to respond to the estrin or stilbestrol therapy alone.
- (6) Artificial fever: As with the autohemotherapy, this measure is employed in those patients who have failed to respond to the estrin hormone or stilbestrol alone.

C. Physical Therapy Measures:

The same principles were applied here as in the other rheumatic phenomena. As a rule, the menopause arthritis patients have a lowered basal metabolism, and it is desirable to use measures which have a stimulating effect on the general metabolism. The more commonly used modalities are listed:

1. Heat: Local and general application. Except in the acute cases heat is usually followed with a brief application of cold. Warm baths of from fifteen to thirty minutes followed with a brief cold shower; contrast baths, hot paraffin, short wave, and hot fomentations, were helpful.

D. Orthopedic Measures:

1. Splinting and rest of acute areas.
2. Support where indicated. It is necessary to pay close attention to this phase of the management. It involves such features as splints, shoes, braces, and corsets. The knee is possibly one of the most important joints in that it is most frequently involved; once the disease process is started, it leads to degeneration of the joint. In our experience, the application of a leather knee cage brace reinforced with metal supports on each side hinged at the knee, has been most useful.

RESULTS

The results in these cases are listed in Table I. Briefly, they can be summed up as follows:

1. Sixty patients received stilbestrol by injection. In this group 80 per cent have had complete remission, 15 per cent improved, and 5 per cent failed to respond.

2. Thirty patients received stilbestrol by mouth. In this group 77 per cent had complete remission, 10 per cent improved, and 13 per cent failed to respond.

3. Thirty patients who had been receiving estrogenic hormones were changed to stilbestrol therapy. The patients were not informed of the change. Of these, 82 per cent noticed no change, 15 per cent stated they were better, and 3 per cent had increased pain.

4. Sixty patients in the control group received estrogenic hormones by injection. Of these, 85 per cent had complete remission, 10 per cent were improved, and 8 per cent failed to improve.

5. Thirty-four patients received estrogenic materials by mouth. Of these, 30 per cent had remission, 35.1 per cent were improved, and 35 per cent failed to improve.

It is interesting to note that those patients who had remission of rheumatic symptoms also had remission of the other symptoms accompanying the menopause. It is also interesting to observe that whereas the estrogenic material given by mouth failed as a whole to control the symptoms, the stilbestrol by mouth was largely adequate. Experience proved, however, that when stilbestrol is given by mouth, it is better to use 0.5 mg. instead of 1 mg., and that the tablets should be enteric coated. In the average case, the patient responded better if the stilbestrol was given daily. These measures largely eliminated the major complication, which was nausea.

TABLE I

THERAPY USED	NUMBER OF PATIENTS	REMISSION	IMPROVED	UNIMPROVED	COMPLICATIONS OR SIDE ACTIONS
1. Stilbestrol by injection	60	48 patients or 80%	9 patients or 15%	3 patients or 5%	Nausea 17% Sore breasts 5% Vertigo 1.6%
2. Estrin by injection	60	49 patients or 82%	6 patients or 10%	5 patients or 8%	Nausea 2% Sore breasts 4% Vertigo none
3. Stilbestrol by mouth	30	23 patients or 77%	3 patients or 10%	6 patients or 13%	Nausea 10% Sore breasts 5% Vertigo 1.6%
4. Estrin by mouth	34	10 patients or 29.4%	12 patients or 35.3%	12 patients or 35.3%	None
5. Autohemotherapy with estrin	14	12 patients or 85%	1 patient or 12.5%	1 patient or 12.5%	
6. Combined autohemotherapy and fever	15	12 patients or 80%	1 patient or 6%	2 patients or 14%	

DISCUSSION

The stilbene derivatives have been under careful experimental observation for the past six years. In 1934 Cook, Dodds, Hewett, and Lawson⁵ described the estrogenic activity of a series of phenanthrene and dibenzanthracene compounds. It was shown that these substances can replace estrone in every way. In 1938 Dodds and Lawson⁶ demonstrated that dihydroxystilbene had definite estrogenic activity.

More investigations were continued and the potent substance, 4,4; dihydroxydiethylstilbene (diethylstilbene stilbestrol), was discovered.⁷⁻¹⁰

Extensive pharmacologic tests of stilbestrol have been carried out on experimental animals, and the following facts have been established:

1. Geschickter,¹¹ in 1939, in discussing mammary carcinoma in the rat with metastasis induced by estrogen, suggests that "the mammary cancers induced in the rats by the injection of estrogenic substances are due to the physiologic changes produced rather than to the cancerogenic nature of the chemicals used."

2. Selye,¹² in 1939, in reporting on the toxicity of stilbestrol, concluded: "Experiments on the mouse and the rat indicate that when given in very high doses both estradiol and diethyl stilbestrol may exert toxic effects. In the mouse, death may occur under the influence of such estrogens."

3. Loeser,¹³ in 1939, in reporting on the clinical effect of diethylstilbestrol, states that this product has a marked substitution action in various forms of ovarian insufficiencies, but that 6 of the 15 patients in whom it was used had nausea or vomiting.

4. Others, MacGregor,¹⁴ Bishop, Boycott, and Zuckerman,¹⁵ Winterton,¹⁶ Kellar and Sutherland,¹⁷ Rees,¹⁸ Karnaky,¹⁹ Ehrhardt, Kramann, and Schäfer²⁰ in 1939 reported favorably on the use of stilbestrol. Karnaky¹⁹ states that it is as potent when given by mouth as by injection and that no toxic effects were felt. Varanget,²¹ reporting in the 1939 literature, however, advises against its use.

In the 1940 literature 33 papers were published from January to June. Of these, I was able to obtain 15. In these, 12 of the authors²²⁻³³ advise the use of stilbestrol, while 3 of them³⁴⁻³⁶ advise against its use. The universal objection is chiefly the side action of nausea and epigastric pain.

In our series 10 patients (17 per cent) complained of nausea. In all these, however, the drug was continued at a reduced dosage. In only one patient was it necessary to discontinue the drug. In using this preparation, however, all the factors contraindicating the use of the estrins must be closely observed and followed.

The terminology of stilbestrol is somewhat confusing due to the synonyms used. Diethylstilbestrol, 5,5, dihydroxydiethylstilbene, and diethylstilbene are used. The empirical formula is $C_{18}H_{20}O_2$. The structural formula:

It is a white, odorless, tasteless, nonhygroscopic powder. Less than 1 mg. will go into solution in 20 c.c. of water. It is soluble in most organic solvents and in vegetable oils. It is soluble in alkali hydroxides.

CONCLUSIONS

1. Forty-eight patients (80 per cent) diagnosed as having menopause arthralgia had satisfactory remissions following the injections of stilbestrol used in conjunction with other supportive measures.

2. Forty-nine patients (82 per cent) as controls responded satisfactorily to estrin injections along with the same supportive measures.

3. In 30 patients stilbestrol was successfully substituted for estrin with only 3 per cent having return of original symptoms.

4. Twenty-three patients (77 per cent) receiving stilbestrol by mouth had clinical remission as compared to 10 patients (30 per cent) who received estrin that responded by clinical remission.

If the foregoing findings are borne out by later investigators, and if complications not yet detected in the patient do not make their appearance, stilbestrol should supplant the use of the estrogenic hormone for two reasons: (1) It is effective when given orally. (2) The cost to the patient is greatly reduced. In considering the fact that the treatment is largely substitutional and must be continued for a comparatively long period of time, these two factors would justify the use of stilbestrol.

CARDIAC DEPRESSION BY MERCURIAL DIURETICS*

ROBERT L. JOHNSTON, M.D., CINCINNATI, OHIO

IN VIEW OF the fact that mercurial diuretics are often used in cases of edema and dropsy of cardiac origin, these experiments were performed on isolated turtle hearts to ascertain whether impaired cardiac action may follow their use in concentrations which prevail therapeutically, and to note the antidotal effect of sodium thiosulfate and certain cardiac stimulants.

A review of the abundant literature is not intended, but certain papers are cited for their pertinent interest. Salant and Kleitman¹ in 1922 studied the action of mercurial salts on the hearts of intact cats and dogs, and on the isolated hearts of frogs and turtles. Turtle hearts developed delirium cordis after twelve minutes of perfusion with mercuric chloride, one part in one million. This persisted for more than twenty minutes during subsequent perfusion with Ringer's solution. Similar effects were observed on the hearts of cats under urethane anesthesia, but of shorter duration. Wolf² in 1932, Molnar³ in 1935, and Greenwald and Jacobson⁴ in 1937, report cases of sudden death following the administration of mercurial diuretics to patients. Deaths following the

Received for publication, November 6, 1940.

therapeutic administration of calomel are reported by Backer⁵ in 1921, Burnet and Pestal⁶ in 1924, and Póvoa⁷ in 1927.

METHOD

Ringer's solution with the pH adjusted between 7.2 and 7.4 served as the vehicle of perfusion for all drugs used. The apparatus and technique were the same as used in previous publications.⁸ Solutions of the mercurial diuretics, salyrgan and mereupurin, were prepared by diluting the 1 c.c. commercial ampoules. The most frequently used concentration in this study, 0.01 c.c. per 100 c.c. of Ringer's solution, had a mercury content of one part in 300,000.

RESULTS

In the charts the ordinates indicate by black dots the heights of cardiac contractions as written by the lever on the smoked drum, while the vertical columns indicate relatively the cardiac work done in terms of stroke distance per minute (M.S.D.); the figures in the abscissa indicate the perfusion time in minutes.

Figs. 1-6.—Fig. 1 shows height of contractions increased by glycine in the presence of salyrgan, 0.01 c.c. per 100 c.c. of Ringer's solution, but due to the slowed heart rate caused by salyrgan the cardiac work (M.S.D.) is decreased.

Fig. 2, both the height of contractions and the rate are decreased by salyrgan, 0.01 c.c. per 100 c.c., in the presence of coramine, but sodium thiosulfate causes immediate recovery.

Fig. 3, salyrgan, 0.01 c.c. per 100 c.c., decreased the height of contractions in 9 of 11 experiments.

Fig. 4, another experiment similar to Fig. 1.

Fig. 5, height of contractions decreased in 5 of 6 experiments by salyrgan, 0.02 c.c. per 100 c.c.

Fig. 6, salyrgan, 0.04 c.c. per 100 c.c., quickly brought height of contractions to zero; added sodium thiosulfate caused immediate recovery.

Salyrgan. Figs. 1 and 4 show that salyrgan perfused in a concentration of 0.01 c.c. per 100 c.c. in the presence of a cardiac stimulant (glycine 0.5 Gm. per cent) increased the height of contractions but decreased the cardiac work (M.S.D.).

Fig. 2 indicates that both the height of contractions and the M.S.D. are decreased by salyrgan, 0.01 c.c. per 100 c.c., in the presence of another cardiac stimulant (coramine 25 mg. per cent). Recovery is prompt with the addition of sodium thiosulfate, 10 mg. per cent, to the perfusate.

Fig. 3 shows 11 experiments wherein the same concentration of salyrgan was perfused. In nine of these, or 82 per cent, the height of contractions was decreased.

Fig. 5 shows five experiments wherein 0.02 c.c. per cent of salyrgan was perfused. In four of these, or 80 per cent, the height of contractions was decreased.

Fig. 6 shows the decrease in height of contractions caused by perfusion with salyrgan, 0.04 c.c. per cent, and prompt recovery when sodium thiosulfate was added.

Figs. 7-9.—Fig. 7 shows effect of mercurpurin, 0.01 c.c. per 100 c.c. of Ringer's solution, on height of contractions and cardiac work (M.S.D.).

Fig. 8 shows heights of contractions in 5 experiments wherein mercurpurin, 0.01 c.c. per 100 c.c. was perfused.

Fig. 9 shows graphs of 6 perfusion experiments with bichloride of mercury in concentrations of 1:40,000 to 1:10,000.

Mercupurin. Fig. 7 shows the results of mercurpurin, 0.01 c.c. per cent, on the height of contractions and the minute stroke distance. In both experiments the amount of work done (M.S.D.) was decreased, but not to the same extent. In one the height of contractions was increased.

Fig. 8 shows the heights of contractions of five experiments on hearts perfused with the same concentration of mercurpurin.

Mercuric Chloride. Fig. 9, graphs 1 to 6 inclusive, shows for comparison the effect of perfusion of the isolated turtle heart with bichloride of mercury in the concentrations of 1:40,000, 1:20,000, and 1:10,000 in Ringer's solution.

The concentration of 1:40,000 slightly increased the height of contractions and the rate with a consequent increase in the M.S.D. The susceptibility of the individual hearts varied, e.g., the concentration of 1:20,000, graph 5, in one heart was more depressing than that of 1:10,000, chart 6, in another heart.

Mercurous Chloride. Fig 10A is the second tracing of a heart tracing showing fully developed delirium cordis by perfusion with calomel in a concentration of 1:10,000, shaken and decanted, and the decanted fluid used as perfusate. When Ringer's solution was subsequently perfused, the irregularity persisted for several minutes, the mercury being difficult to wash out; but when sodium thiosulfate was perfused, the antidotal effect was immediate.

Fig. 10B is a specimen tracing from which the charts of Fig. 2 were derived. Notwithstanding the presence of coramine, 25 mg. per 100 c.c. with the mercurial diuretic, there was typical mercury depression evidenced by decrease in height of contractions followed by partial, then complete, heart block. Continuation of perfusion with the same solution plus sodium thiosulfate, 10 mg. per 100 c.c., resulted in immediate recovery. These tracings, 10A and 10B, are shown because they typically illustrate the cohesion of mercury salts in the cardiac tissues, and that sodium thiosulfate rapidly penetrates the tissues performing its well-known antidotal action.

Fig. 10.—A (upper chart) shows the heart tracing after the full development of delirium cordis by perfusion with decanted Ringer's solution in which calomel 1:10,000 had been shaken. The mercury effect was not readily removed by perfusion with Ringer's solution until sodium thiosulfate was added; whereupon recovery was immediate. B (lower chart) is the experiment from which the graph in Fig. 2 was mathematically derived.

COMMENT

That the mercurial diuretics occupy a position of great usefulness in the treatment of selected cases of edema and dropsy cannot be denied. It is desired to emphasize that their effectiveness is due to their mercury content, and that their toxicity is not appreciably different from that of a similar concentration of mercury in other forms. No claim is made here that tolerance to mercury is

identical in the different species insofar as the cardiac tissues are concerned, nor is this research intended to discourage the proper use of the mercurial diuretics, under close medical supervision, in suitable cases.

CONCLUSIONS

A study was made of the toxic effects of mercurial diuretics and the protective effects of various heart stimulants on isolated turtle hearts.

1. The mercurial diuretics possess a toxicity to the heart with reference to their mercury content that is not essentially different from that of inorganic mercury compounds. This side action is apart from diuresis and may sometimes impede it.

2. The purine derivatives especially, and to some extent certain of the other cardiac stimulants, when used in conjunction with mercurial diuretics, somewhat decreased the toxicity to the heart when the dose of the latter was sufficiently small to be of low toxicity. These cardiac stimulants, however, had relatively little antidotal action.

3. Sodium thiosulfate perfused through the mercury-poisoned heart in complete block rapidly penetrates the tissues and restores the normal force and rhythm whether the toxic agent is one of the mercurial diuretics, or calomel, or bichloride of mercury. This antidotal action takes place even if the mercury compound is continuously perfused in the presence of the antidote.

Thanks are extended to Dr. Martin H. Fischer for constructive criticism and suggestions during the conduct of this research.

THE EFFECT OF SUPPLEMENTAL AMYLASE ON DIGESTION*

J. M. BEAZELL, PH.D., M.D., CHICAGO, ILL.

JUDGING from the comments in many textbooks of materia medica and therapeutics, it must be concluded that, at the present time, most authors question the value of enzyme therapy. This is probably due, at least in part, to a report by Bastedo.¹ He submitted a questionnaire pertaining to the value of digestive enzymes, to a representative group of gastroenterologists. On the basis of their replies, he was forced to conclude that at the time of his survey, these agents were of minor importance in therapeutics.

Two widely held conceptions appear to be largely responsible for the low esteem in which enzyme therapy is held. It is generally believed that (a) deficient digestion is rarely, if ever, a cause of symptoms, and that (b) in most cases enzyme therapy is necessarily doomed to failure because the administered enzyme would be quickly inactivated by the acid gastric juice. That both of these concepts are erroneous has been established conclusively. It has been shown repeatedly in laboratory animals in which pancreatic juice has been prevented from reaching the intestine that enzyme therapy exerts a potent effect on the quantity of food assimilated.² Silverman, Denis, and Leche³ have shown that a number of different pancreas preparations augment the concentration of enzymes in the intestine, and Ivy, Schmidt, and Beazell⁴ have shown that, when properly administered, approximately 85 per cent of ingested enzyme reaches the intestine in an active form. More recently, Beazell, Schmidt, and Ivy² have discussed the value of enzyme therapy in the treatment of achylia pancreatica. In 4 patients suffering from a complete suppression of the external secretion of the pancreas, they found that adequate enzyme therapy reduced the quantity of fat and nitrogen eliminated in the feces by an average of 63.3 per cent and 62 per cent, respectively. Further, the clinical response of the patients was gratifying in all cases.

The investigation herein discussed was undertaken to test further the potentialities of enzyme therapy. It was instituted to provide answers to two problems: (1) What is the effect of supplementary diastase on starch digestion in the stomach? (2) Is that fraction of the supplementary diastase which reaches the intestine in an active form capable of effective hydrolysis? The first of these two problems has already been attacked by Ivy, Schmidt, and Beazell.⁴ They were primarily concerned with the effect of diastase on the rate of digestion, rather than on the total quantity of starch digested. Furthermore, in most of their studies they employed a cereal (farina) as a test meal, so their observations cannot be unequivocally used as a basis for anticipating

*From the Department of Physiology and Pharmacology, Northwestern University Medical School, Chicago.

Received for publication, October 25, 1940.

the effect of supplementary diastase in the presence of a mixed meal. For these reasons, it appeared desirable to repeat and extend their experiments.

For a number of reasons taka-diastase* was chosen as the test enzyme preparation. First, it is a potent diastatic ferment having an activity of 0.96 Willstätter⁵ and 11,260 Davison⁶ units per gram; second, it is active over a relatively wide pH range; and third, in powder form it can be stored indefinitely without alteration in activity.

EFFECT OF TAKA-DIASTASE ON GASTRIC DIGESTION IN NORMAL HUMAN BEINGS

Methods.—The details of the experimental methods and calculations have been described and discussed in a previous communication.⁷ Briefly, the experiment consisted of feeding normal young adult males a meal of known composition, withdrawing it from the stomach at the end of a specified period of time, and determining the ratio of "digested" to "undigested" carbohydrate and, in certain experiments, protein in the recovered material. The effect of the taka-diastase was determined by comparing the results of one or more control experiments with one or more in which taka-diastase was taken with the standard meal.

Twelve clinically normal young adult males were used as subjects for the experiment. In the initial phases a test meal consisting of 150 Gm. of beef steak, 150 Gm. of boiled potatoes, 50 Gm. of green peas, 10 Gm. of butter, and 200 c.c. of water was employed. When used, 2 Gm. of taka-diastase were dissolved in the water which was sipped throughout the meal. Five persons who were capable of voluntarily regurgitating the gastric contents for analysis were tested with this meal. During preliminary experiments it became apparent that under the conditions of the experiment taka-diastase effected no augmentation of gastric starch digestion. Apparently in these normal healthy human beings, the ingestion of an appetizing meal stimulated the flow of sufficient saliva to effect maximum digestion so that supplementary amylase had no demonstrable effect. Therefore, in order to determine whether taka-diastase was capable of hydrolyzing starch in the stomach, it was necessary to have the subjects voluntarily induce a salivary deficiency. This was accomplished by having them "bolt" the meal, and then during the hour the meal remained in the stomach, swallow as little saliva as possible.

Subsequently, this meal was abandoned in favor of a finely divided homogeneous meal for the following reasons: (a) Only a limited number of subjects were capable of cooperating in an experiment requiring regurgitation of the meal. (b) By resorting to a finely divided meal it was possible to evacuate completely the stomach by means of an Ewald tube, and to (c) determine the dilution of the meal by the gastric juice. This latter determination made it possible to calculate the fraction of the ingested taka-diastase remaining in the stomach in an active form at the termination of the experiment, and the fraction of the digested material recovered from the stomach that represented preformed digested material contributed by the meal.

*Product of Parke, Davis & Co.

The finely divided meal consisted of 100 Gm. of ground lean beef and 30 Gm. of potato starch boiled in sufficient water to yield a final volume of 400 c.c. Twenty milligrams of phenolsulfonephthalein was dissolved in the water used in preparing the meal. The dilution of the dye served to determine the dilution of the meal by the gastric juice and saliva. When this meal was employed, it was unnecessary to induce a state of artificial salivary deficiency in order to demonstrate augmentation with taka-diastrase.

Results.—The results obtained with the unground meal are summarized in Table I. Of the 5 persons tested, 3 showed a decided increase in the quantity of starch digested in the stomach when taka-diastrase was added to the meal, and the remaining 2 showed no change. The results are significant, since whenever a change occurred it was always in favor of more complete digestion when taka-diastrase was taken with the meal.

*As maltose.

The results obtained with the finely divided meal are summarized in Tables II and III. Taka-diastrase had no effect on the digestion of protein, which is not surprising since it possesses only feeble proteolytic activity.

In the case of starch digestion, on the other hand, taka-diastrase effected a significant augmentation in all persons with a 2 Gm. dose, and in at least 5 of the 8 persons with a 1 Gm. dose. In the cases in which duplicate control determinations were conducted, satisfactory checks were obtained in all persons except one. This one was also erratic in his response to taka-diastrase, a greater effect being obtained with 1 Gm. than with 2 Gm. It should be noted, however, that in the presence of taka-diastrase digestion was more complete than in either of the control experiments.

In no case did a significant fraction of the taka-diastrase remaining in the stomach retain its activity.

EFFECT OF TAKA-DIASTASE ON GASTRIC DIGESTION IN THE DOG

Having established that conditions in the human stomach are not incompatible with effective hydrolysis by taka-diastrase, it became desirable to study its action under circumstances which made it possible to determine total gastric

digestion. In the studies on the human subjects only the state of digestion at the end of a specified period of time could be determined. In order to determine total digestion in the stomach, a duodenostomy or duodenal fistula must be present so that the total gastric discharge can be collected for analysis as it is evacuated through the pylorus. Therefore, in 3 dogs the bile was diverted to the lower jejunum by means of a cholecystojejunostomy, the pancreatic juice was prevented from reaching the intestine by resecting the portion adherent to the duodenum, and a duodenostomy was created. By introducing a large catheter (28 F) into the duodenum through the fistula, it was possible to collect the uncontaminated gastric contents as they were evacuated through the pylorus. Since the dog's saliva contains no ptyalin, results in the dog might, with justification, be used to predict what would occur in the ptyalin-deficient patient.

Methods.—The meal used in these experiments was identical to the finely divided meal used in the experiments on human beings. In the case of one animal it was necessary to dilute the meal and administer it by means of a stomach tube. In the experiments in which taka-diastase was tested, 2 Gm. were mixed with the meal immediately before administration. Continuous collection of the discharge from the fistula was instituted immediately after the meal was ingested and continued until the stomach was empty. The material was permitted to accumulate in the collecting receptacle for periods of thirty minutes before being sampled for analysis. The analytical methods have been described and discussed previously.⁷

Results.—The results of this experiment are summarized in Table IV. In the case of each animal the results represent an average of three control determinations and three determinations with taka-diastase. It is unnecessary to record the results of individual experiments, since the variations were inconsequential. These results reveal the following facts: (1) The fraction of the ingested starch digested in the stomach was markedly augmented by taka-diastase in all cases. The average for the 3 animals was 7.58 per cent digestion without taka-diastase, and 38.9 per cent digestion with taka-diastase. These values demonstrate that in the absence of ptyalin, starch digestion in the stomach is of no significance, and that adequate substitution therapy will reduce a large fraction of the starch to simple sugars. (2) The fraction of ingested taka-diastase reaching the intestine in an active form is subject to wide individual variation, being dependent on the rate of secretion of acid by the stomach. In animal No. 2, in which the fall in pH approaches that in man, the diastase was almost entirely inactivated in the stomach. It must be concluded that when administered in this manner the effect of taka-diastase is confined almost entirely to the period during which it remains in the stomach. (3) The addition of taka-diastase to the test meal had no significant effect on the rate of emptying of the stomach.

EFFECT OF TAKA-DIASTASE ON STARCH DIGESTION IN THE SMALL INTESTINE

Having demonstrated that taka-diastase has a positive and significant effect on starch digestion in the stomach, the effect of that fraction that escapes inactivation by the gastric juice was investigated.

Methods.—Dogs were anesthetized with pentobarbital, the abdomen was entered through a midline incision, and a segment of intestine from 70 to 90 cm. long was isolated and cannulated at both ends. The segment was washed first with 500 c.c. of water, then 500 c.c. of tenth-normal hydrochloric acid, and then another 500 c.c. of water. From 70 to 100 c.c. of either 3 or 4 per cent potato starch paste was then introduced and permitted to remain for one hour. The unabsorbed fraction of the paste was permitted to drain out, after which the segment was flushed out with 100 c.c. of water, which was collected and combined with the residual paste that had been collected. The segment was then washed with an additional 500 c.c. of water, and the experiment was repeated with 500 mg. of taka-diastase added to the starch paste immediately before introduction. The recovered samples were assayed for amylase, and the reducing sugar and the pH were determined.

*As glucose.

Results.—The results of six such experiments are summarized in Table V. It will be seen that with the exception of the first two experiments, in which pancreatic amylase must have been present in the segment because of inadequate initial washing, starch digestion affected by succus entericus amylase is very limited. It is also seen that taka-diastase is very active in the intestine. Furthermore, the taka-diastase survives one hour in the intestine with only limited loss of activity.

EFFECT OF TAKA-DIASTASE ON TOTAL DIGESTION OF STOMACH PLUS SMALL INTESTINE

Gastrointestinal digestion has been studied in one patient with a well-established ileostomy. In such a patient the ileal discharge represents the material which would normally pass into the colon and there be available for bacterial degradation. Such a patient offers an ideal "experimental preparation" for the study of factors affecting the quantity of carbohydrate reaching the colon.

Methods.—After hospitalization the patient was placed on a standard weighed diet supplying carbohydrate 177 Gm., protein 66 Gm., and fat 172 Gm. for a period of six days. During the first three-day period he received the unaugmented diet. During the second three-day period he received 2 Gm. of taka-diastase, taken in water, with each meal. The entire output of the ileostomy was collected during the entire experimental period. The material was transferred as soon as excreted to airtight bottles containing sufficient alcohol to make the final concentration 20 per cent. The wet weight, dry weight, starch and nitrogen content of the material were determined for each twenty-four-hour period. Amylase assays at pH 7.2 (pancreatic amylase) and 4.5 (taka-diastase) were carried out during the last two days of taka-diastase therapy.

TABLE VI

EFFECT OF TAKA-DIASTASE ON STARCH AND NITROGEN CONTENT OF MATERIAL DISCHARGED FROM ILEOSTOMY

DATE	WET WEIGHT FECES	DRY WEIGHT FECES	TOTAL STARCH	TOTAL NITROGEN	AMYLASE (WILLSTÄTER UNITS 1 C.C.)	
					pH 4.5	pH 7.2
10/29	706	36	2.7	1.50	—	—
10/30	641	44	3.8	1.81	—	—
10/31	878	56	4.8	2.12	—	—
11/1*	726	56	6.0	1.92	—	—
11/2*	706	48	4.8	1.59	0.45	1.8
11/3*	746	44	2.1	1.70	0.55	1.8

*Taka-diastase (2 Gm.) with each meal.

Results.—The results of this study are summarized in Table VI. It will be seen that taka-diastase had no effect either on the nitrogen or on the starch lost in the ileal fluid. This is not remarkable when one notes that even without taka-diastase the amylolytic activity of the collected material was high, as demonstrated by the assay, at pH 7.2 where the effect of the pancreatic amylase would dominate that of the taka-diastase. In other words, the normal pancreas supplies sufficient secretion to maintain potent amylolytic power in the ileal contents. It appears, therefore, that the same fraction of ingested starch that escapes digestion by pancreatic amylase also escapes digestion by taka-diastase.

DISCUSSION

It should be clearly understood that the subjects used throughout the experiments on gastric digestion were all healthy young adults, in whom there would be no reason to suspect that enzyme supplementation would be of any practical value. These experiments were undertaken to determine whether conditions in the human stomach are compatible with effective hydrolysis by taka-diastase. It would not be expected that an enzyme preparation would markedly augment digestion in the *normal* stomach. These points are emphasized because, in a sense, this type of experimentation presents the case for enzyme therapy in its least favorable light. Enzyme therapy is a form of substitution therapy and should be reserved for cases in which an enzyme deficiency, whether on the basis of organic disease or poor hygiene, is suspected.

The fact that taka-diastase had no effect on protein digestion is, of course, not unexpected. Taka-diastase possesses only feeble proteolytic activity. The

problem was investigated for two reasons: First, because, theoretically, by liquefying the starch paste adherent to the protein particles it seemed possible that greater surface area would be exposed to the action of pepsin with consequent greater digestion. Second, it will be seen on examining Tables I and II that almost uniformly the pH was higher when taka-diasatase was taken with the meal. When this phenomenon was encountered in the earlier experiments, it was interpreted as possibly being due to greater buffering power resulting from more complete hydrolysis of the protein. As a result, protein as well as starch digestion was investigated in the subsequent experiments. Since the experimental results failed to substantiate the theory, a satisfactory explanation for the pH observations is wanting at the present time. Taka-diasatase has essentially no buffering power, and it seems unlikely that it actively inhibits acid secretion.

The difference between the whole meal and the finely divided meal with respect to the magnitude with which taka-diasatase supplemented "normal" digestion is probably a result of two factors. First, it will be noted (Tables I and II) that with the unground meal the pH of the gastric contents fell more slowly. This permitted the ptyalin to act for a longer period so that, unaided, "maximum" digestion could be effected. Second, it appears likely that the more appetizing unground meal constituted a more potent stimulant for salivary secretion so that larger quantities of ptyalin were available for digestion.

When aided by taka-diasatase, gastric starch digestion in the dog was more complete than it was in man. This is probably due to the fact that in the dog the pH of the gastric contents fell more slowly, thus permitting the taka-diasatase to act for a longer period.

Since in the human studies and in the one dog (No. 2) in which acid secretion approximated that in man only negligible quantities of taka-diasatase were recovered from the stomach in an active form, it must be concluded that when administered in this manner the effect of taka-diasatase is largely confined to the period that it remains in the stomach. However, as has been demonstrated by Ivy, Schmidt, and Beazell,⁴ when half the dose of diasatase is administered on a full stomach, a large fraction reaches the intestine in an active form. The studies on the effect of taka-diasatase on digestion in the intestine show that the fraction which escapes inactivation in the stomach continues to be effective.

The failure of the administered diasatase to modify digestion in the patient with an ileostomy could be anticipated. Both the total nitrogen and the total carbohydrate of the material recovered from the ileostomy corresponded with normal values for feces. In other words, in this patient, by the time the terminal ileum had been reached digestion was carried to completion. Thus, supplementation of the digestive ferments could not have an effect.

SUMMARY AND CONCLUSIONS

The effect of supplementary amylase on gastric digestion was studied in "normal" human subjects and in dogs with duodenal fistulas.

1. When the tests on the human subjects were conducted with an average mixed meal, it was found that taka-diasatase had no effect on digestion unless

an artificial salivary insufficiency was induced by having the subjects bolt the meal and then refrain from swallowing saliva. Under these latter circumstances taka-diastase augmented gastric starch digestion to a significant extent in 3 of 5 subjects. This meal was recovered from the stomach by voluntary regurgitation on the part of the subjects.

2. With a finely divided mixed meal that could be recovered from the stomach by means of an Ewald tube, taka-diastase effectively augmented starch digestion in all subjects with a 2 Gm. dose, and in 5 of 8 subjects with a 1 Gm. dose. With this meal it was unnecessary to induce a salivary deficiency in order to demonstrate the effect of the enzyme.

3. In the dog the average starch digestion without taka-diastase was 7.58 per cent and with taka-diastase it was 38.9 per cent. The marked difference between the control and taka-diastase experiment is due to the failure of the dog to secrete ptyalin in its saliva. In this respect, results in the dog are indicative of what might be expected in a patient with a marked ptyalin insufficiency.

4. Taka-diastase had no significant effect on gastric protein digestion in the human subjects.

5. Taka-diastase had no significant effect on the rate of emptying of the stomach.

6. In the experiments on the human subjects the quantity of taka-diastase recovered from the stomach in an active form was inconsequential. In the dog, the quantity of taka-diastase evacuated from the stomach in an active form was a function of the rate of secretion of acid by the stomach. This shows that if it is desired to have the enzyme reach the intestine in an active form, it should be administered in water at the completion of the meal, as was shown by Ivy, Schmidt, and Beazell.⁴

The effect of taka-diastase on starch digestion in the intestine was studied by introducing a solution containing a known quantity of starch with and without taka-diastase into an isolated intestinal loop of an anesthetized dog, withdrawing it at the end of an hour, and determining the quantity of reducing sugar that had been formed.

1. Starch digestion without taka-diastase was very limited (maximum 4 per cent). In the presence of taka-diastase from 16 to 38 per cent of the starch was reduced to sugar in the one-hour period.

2. The taka-diastase survived one hour in the intestine with only a limited loss of activity.

Gastrointestinal starch digestion was studied in one patient with a well-established ileostomy. The patient was hospitalized, placed on a standard diet, and the entire discharge from the ileostomy was collected for a period of six days. During the last three days of the experimental period the diet was supplemented with 2 Gm. of taka-diastase taken in water with each meal.

1. Taka-diastase had no effect on the quantity of nitrogen or starch lost in the ileal discharge.

2. The potency of the pancreatic amylase in the ileal fluid was about three times as great as that of the taka-diastase.

3. It appears, therefore, that the fraction of ingested starch that escapes digestion by amyllopsin also escapes digestion by taka-diastase.

EXPERIMENTAL ASTHMA: TREATMENT WITH HISTAMINASE*

F. LEVERING NEELY, M.D., NEW YORK, N. Y.

INTRODUCTION

ALTHOUGH most of the major principles of the induction, symptoms, and pathology of experimental asthma in guinea pigs have been investigated, the use of such a model in the evaluation of therapeutic agents has been neglected. The widespread usage of the preparation histaminase or "Torantil"† on a variety of allergic diseases led to such an experimental trial.

The advantages of experimental asthma over anaphylactic shock as a means of studying allergic phenomena are as follows: First, antianaphylaxis does not occur; i.e., animals will react over and over again in a predictable manner with no diminution in sensitivity. This has been repeatedly shown by all investigators in the field and emphasized by Manteufel and Preuner,¹ Kallós and Pagel,² and Ratner,³ and is confirmed below. Thus, the use of the large numbers of animals necessary for any experiment in anaphylaxis is obviated, since an asthmatic animal may be put to repeated tests if a suitable control period is carried out before and after each test. Secondly, the reaction of an animal during an episode of experimentally induced allergic asthma bears a closer resemblance to asthma in man than does anaphylaxis. Furthermore, the degree of severity of the attack is roughly measurable. Finally it produces characteristic pathologic changes in the lungs, simulating the lesions seen in human beings.

Busson⁴ in 1911 is said to have been the first to produce asthma by inhalation experiments. Following a number of successful and unsuccessful results

*From the Department of Pathology, College of Physicians and Surgeons, Columbia University, New York.

Received for publication, October 31, 1940.

†"Torantil" was kindly supplied by the Winthrop Chemical Company.

by several workers, Alexander, Beeke, and Holmes⁵ in 1926 caused death by inhalation of horse dander extract in guinea pigs previously sensitized either by inhalation or by intraperitoneal injection. They found that strong antigens were necessary, and even then a number of their animals failed to have any reaction. Ratner and co-workers⁶ in 1927 produced sensitization, shock, bronchial asthma, and death by nasal inhalation of dry horse dander in guinea pigs. They believed that dry antigen reproduced human conditions better than liquid antigen. Manteufel and Preuner⁴ in 1933 called attention to the fact that the spray droplets must be very small in order to produce asthmatic attacks in guinea pigs, and believed that previous failures were due to this fact. They stressed the absence of antinaphylaxis and produced asthmatic attacks repeatedly.

Kallós and Pagel² published in 1937 the results of a series of investigations on experimental asthma. These authors compared the reactions of guinea pigs subjected to allergic asthma and to inhalation of histamine and of acetylcholine. They described the clinical nature of the attacks, demonstrated the absence of antinaphylaxis, showed hereditary transmission of bronchial sensitization, and gave descriptions of the pathology showing certain differences between the three groups of animals. Finally, they demonstrated the ability of atropine, adrenaline, and a calcium preparation to inhibit the attacks.

Recently, Preuner⁷ continued his studies and has reported the results of investigations made to learn the effect of the weather on experimental bronchial asthma. By grading the reaction of his animals and recording his results statistically, he concluded that changes in the weather had the effect of increasing the severity of the attack. The effects, however, of change of weather were relatively slight, but his observations established the possibility of measuring the severity of the attack. Ratner's³ recent review is comprehensive, and he has worked out the time element in sensitization by inhalation of dry antigen.

The question as to whether release of histamine is responsible for anaphylactic shock and allergic phenomena cannot be reviewed here, but some of the more recent evidence is summarized by Laymon and Cumming.⁸

HISTAMINASE

The literature concerning histaminase has been accumulating rapidly since the description by Best and McHenry⁹ of a substance in animal tissues capable of inactivating histamine when incubated with it for twenty-four hours at 37° C. The substance was observed to have the properties of an enzyme and was found in almost all organs but was most abundant in the intestinal mucosa and the kidney.

Felix¹⁰ found that histaminase had a questionable therapeutic effect on skin diseases and stated that it failed to reduce the gastric acidity of either normal or ulcer patients. Adelsberger¹¹ and Ertl¹² reported favorable results in such allergic diseases as eczema and hay fever. Foshay and Hagebusch¹³ found it of definite value in serum sickness. Roth and Horton¹⁴ have used it effectively in the treatment of cold allergy.

Other reports are not so promising. Laymon and Cumming⁸ found histaminase to be beneficial in only certain cases of urticaria. Kile and Rusk¹⁵

found no improvement in cold allergy after histaminase. A recent article denying the clinical value is that of Miller and Piness,¹⁶ who tried it on a large number of patients with varying allergic disorders. Keeney¹⁷ found no relief of hay fever after its use.

The experimental basis for the use of histaminase has been meager, and its toxicity has not been fully investigated. Karady and Browne¹⁸ reported almost complete prevention of histamine shock in guinea pigs when histaminase was given intravenously fifteen minutes before the administration of a shocking dose of histamine, and a similar result was obtained in inhibiting anaphylactic shock due to egg white in a group of 30 animals. Of 10 animals as controls, 4 died; of the 20 pretreated with histaminase, none died when the homologous antigen was reinjected. The guinea pigs were given 3 units of histaminase intravenously while under ether anesthesia. However, ether anesthesia has been observed to inhibit anaphylactic shock.¹⁹ Corper and Cohn²⁰ were not able to demonstrate any effect of histaminase on histamine intoxication, tuberculo-anaphylaxis, or tuberculo-allergy.

Inasmuch as the clinical picture presented in animals subjected to experimental allergic asthma is very similar to that seen in human beings with asthma, it was decided to study the influence of histaminase on the experimentally produced disease, where conditions may be more carefully controlled than in patients.

ALLERGIC ASTHMA

Following a modification of Kallós and Pagel's² methods, young guinea pigs, weighing approximately 10 Gm., were sensitized with 3 intraperitoneal injections at two-day intervals of 0.5 c.c. of fresh egg white diluted 1:5 with distilled water. Ten to fourteen days after the last injection the animals were sprayed with a 10 per cent solution of egg white in normal saline while in a double chamber. The chamber consisted of an inner open glass jar having a capacity of approximately 6 liters placed in a rectangular metal box measuring 77 by 46 by 46 cm. The material was sprayed directly into the inner chamber from which it passed into the larger box. The latter was provided with a small outlet tube. The vaporizer used was a painter's airbrush connected with a compressed air pump. The airbrush was adjusted to give its finest spray, which at the same time was abundant and was such as to vaporize about 5 c.c. of the fluid during a ten-minute period. The animal was sprayed directly and watched from minute to minute.

Symptoms.—Most of the animals developed asthmatic symptoms within three minutes after beginning the spray; the attack became maximal after five to ten minutes, continued as long as the spray was continued, even as long as an hour, and subsided in about thirty minutes following withdrawal from the chamber.

A typical reaction was as follows (numbers refer to the grade or degree of reaction used in recording): The first symptoms were motor unrest, ruffling of the fur, sneezes, and scratching the nose (1+). This was followed by a definite increase in the respiratory rate, more frequent sneezes, and onset of cough, usually paroxysmal and violent. The animal often chewed as if salivating (2+).

The cough would continue, although sometimes it subsided, but now in addition to the increased respirations definite dyspnea became manifest; the accessory muscles of respiration came into play, the abdominal muscles were quite active, the alae nasi would dilate, and the expiration was often prolonged. During this stage the animals defecated and urinated (3+). Finally during the most severe and usually maximal phase, respirations were labored, and now slower than in the previous stage, the whole body jerked with inspiration; deeper gasps occurred, coming at irregular intervals. Cyanosis was sometimes perceptible in the ears (4+).

Fig. 1.—Allergic asthma: onset and course of a typical attack.

Some of the animals developed a mild conjunctivitis with lacerimation and edema of the eyelids; this usually persisted after all other symptoms had subsided. Musical whistles and squeaks were audible by stethoscope, and there was some roughening of the respiratory sounds. If the animals were graded by the afore-mentioned numbers, the usual course of events is shown in Fig. 1.

Not all the animals responded alike; in some the onset was more abrupt and in others very slow respirations developed. None of the animals died.

Differential blood counts before and after an attack showed a slight increase of eosinophiles and basophiles within twenty minutes.

Corroborating the work of previous investigators, no antianaphylactic phenomena or desensitization due to repeated attacks was found to occur, even in an animal subjected to 21 attacks of asthma at intervals of from one hour to several days.

Pathology.—One animal was sacrificed immediately after its second attack of asthma. Both attacks were maximal, and one month apart. The changes were presumed to be acute, since the animal had had no exposure or symptoms in the interval. Grossly, the lungs filled the entire chest cavity; there was some stringy material in the large bronchi, a few small subpleural hemorrhages, and on section the cut lung surface presented a few areas of reddish discoloration.

Histologically, the most striking change was a wreathing of the bronchi of all sizes with large numbers of eosinophiles, but in addition there were numerous polymorphonuclear cells, and a few lymphocytes and mononuclear cells in an

edematous peribronchial tissue. The capillaries in this area were often plugged with polymorphonuclear cells, and the endothelial cells were swollen and rounded. The bronchial epithelium was swollen and vacuolated; eosinophiles had wandered through the epithelium and were found in moderate numbers in the lumen. The latter was partially filled with mucin, desquamated epithelial cells, red blood cells, and precipitated protein. The bronchioles were often plugged with a similar exudate. Acute emphysema was manifested by stretched and ruptured alveolar walls. Occasional septal accumulations of polymorphonuclear cells, lymphocytes, and eosinophiles were noted. Small areas of atelectasis were also present, with dilated blood-filled capillaries. A few small localized alveolar hemorrhages were present. No eosinophilic pneumonia was seen. Neither true Charcot-Leyden crystals nor Curschmann's spirals were found. Sections of the liver, spleen, heart, and intestine were normal.

HISTAMINE ASTHMA

Another group of 7 guinea pigs was subjected to a total of 21 separate sprayings with 0.1 per cent of histamine phosphate at intervals of from one to five days. The symptoms were in a general way similar to those of the sensitized animals sprayed with egg white, but there were notable differences. The onset was usually much more abrupt, severe, and uncontrollable. Some of the animals reacted within three minutes; others not until fifteen minutes had elapsed. Once the reaction began, its progression was very rapid and following severe dyspnea, shock developed with apnea, deep cyanosis and spasms, and the animal fell on its side. The animal appeared moribund and the spray was discontinued. The recovery was equally as rapid as the development of the shock, occurring in three to five minutes. If the animals were sprayed again, the same severe symptoms recurred. The spray was diluted by degrees in the hope of producing a nonshocking reaction resembling allergic asthma, but the animals gave either no reaction or a very severe one. It was almost impossible to produce a definite predictable reaction from day to day as in the allergic asthma. The method thus presented no advantages over parenteral histamine shock, and was deemed unsuited for evaluation of therapeutic agents.

Kallós and Pagel² emphasized the differences between histamine and allergic asthma, the most notable difference being the scarcity of eosinophiles in the former. We found that the differences were one of degree rather than of kind, and they were not marked. Grossly, the lungs were again overdistended and showed a few scattered petechiae. A little frothy mucinous material was present in the large bronchi. Histologically, emphysema was again marked, with areas of atelectasis. Peribronchial eosinophilia was present but not quite so intense as in the other animals; the numerous polymorphonuclear cells seen in allergic asthma failed to occur. Hemorrhages were less frequently found. There was, however, edema of certain alveolar septa. Other organs exhibited no changes, but the peribronchial lymph nodes were heavily infiltrated by eosinophiles.

HISTAMINASE TREATMENT OF ALLERGIC ASTHMA

Histaminase or "Torantil" is a yellowish white powder supplied in ampoules of 1 histamine-detoxifying unit (1 unit of histaminase is that amount which

will inactivate 1 mg. of histamine at 37° C. in twenty-four to forty-eight hours). It is soluble in saline.

In testing the preparation, the first step was the determination of its activity *in vitro*. The drug was weighed out in portions equivalent to 1.0 unit and 0.7 unit. Each quantity was added to 49 c.c. of phosphate buffer at pH 7.35. One milligram of histamine phosphate in 1 c.c. of water was added to each of the two solutions, and to a control solution of buffer alone. The three solutions were saturated with oxygen, sealed and placed in a mechanical shaker in the incubator at 37° C.

Fig. 2.—Effect of histaminase (Winthrop's Torantil) on histamine contraction of intestinal strip. 1, 0.3 c.c. 1:10,000,000 histamine; 2, 0.3 c.c. 1:10,000,000 histamine; 3, 0.3 c.c. 1:10,000,000 histamine incubated 48 hours at 37° C.; 4, 0.3 c.c. 1:10,000,000 histamine from histamine-histaminase mixture (1 mg. histamine + 1 unit histaminase) incubated 48 hours at 37° C.; 5, same as 4, using 1 mg. histamine + 0.7 unit histaminase; 6, 0.3 c.c. 1:10,000,000 histamine.

The solutions were tested upon the isolated intestinal strip of the guinea pig. At the end of twenty-four hours there was almost complete inactivation in the 1 unit histaminase mixture, and in forty-eight hours it was complete (Fig. 2). It was thus seen that the drug was active *in vitro* according to specifications.

METHOD OF TREATMENT

Twelve guinea pigs which had been found to develop allergic asthma of a predictable degree were used. Eight of them were given intravenous control injections of saline while under ether anesthesia. Fifteen minutes later, having recovered from the effects of the anesthesia, they were sprayed in the usual fashion.

After an interval of several days, during which time they were again sprayed and found to develop asthmatic attacks equal in severity to the reactions prior to the saline injection, these 8 animals, and 4 others, were injected

intravenously with 3 units of histaminase in 2 c.c. of saline. Fifteen minutes later they were sprayed in the usual fashion, and the severity of the reactions was recorded at two-minute intervals for ten minutes. Twenty-four hours following injection of the histaminase, 6 of the group were sprayed again to detect any delayed effect.

Fig. 3.—Effect of histaminase on onset and course of the typical allergic asthmatic reaction.

RESULTS

The result of a typical reaction in one animal, showing its onset and course before and after histaminase, is seen in Fig. 3. The results of all animals is seen in Table I.

TABLE I

EFFECT OF INJECTION OF HISTAMINASE ON ALLERGIC ASTHMA IN GUINEA PIGS, TOGETHER WITH CONTROLS RECEIVING ONLY SALINE

GUINEA PIG NUMBER	TOTAL NUMBER OF ATTACKS	USUAL REACTION	REACTION AFTER SALINE	REACTION AFTER HISTAMINASE	
				15 MIN.	24 HR.
33	7	++++	++++	++++	++++
34	7	++++	+++	++++	++++
35	7	++++	+++	++++	++++
36	7	++++	++++	++++	++++
37	7	+++	++	++	++
38	7	+++	++	++	++
19	9	++++	+++	+++	
22	8	++++	+++	++	
9	21	++++		+++	
17	6	++++		++++	
23	4	++++		++++	
24	4	++++		++++	

It is seen that 5 animals, Nos. 34, 37, 38, 19, and 22, had a lessening in the severity of the attack of one degree after the intravenous injection of the saline solution alone, while 4 animals, Nos. 37, 38, 19, and 9, had a similar diminution in the attack after treatment with histaminase. One animal, No. 8, had a 2+ reaction after histaminase, when its usual reaction was 4+. It would appear from the results with saline alone that either the ether anesthesia or the saline is the cause of this slight decrease, which is itself scarcely significant. There appears to be no latent or delayed effect of histaminase after twenty-four hours,

although the number of animals so tested was relatively small. The onset and course of the allergic reaction appear unchanged by injection of histaminase. In no case was asthma prevented, and in most cases it was the same with or without treatment.

Fig. 4.—Allergic asthma.

Fig. 5.—Histamine asthma.

The animals injected with histaminase did not seem to recover from the anesthesia as quickly as those injected with saline, but no severe reactions were noted on the first or second injection of the preparation, if it was in the course

of a few days. However, there were 3 animals which received histaminase about three weeks after the first injection; these animals developed severe shock which had all the characteristics of anaphylactic shock, coming on in about five minutes. One died. That this is a true sensitization to the histaminase is not surprising, since histaminase is a protein.

Thus it appears that active histaminase, when administered in amounts said to prevent anaphylaxis, fails to show activity in the prevention of experimental asthma in guinea pigs under the conditions stated.

SUMMARY

1. Guinea pigs sensitized intraperitoneally to egg white react to inhaled vaporized antigen in a predictable manner with repeated attacks and show no evidence of desensitization.

2. The symptoms of the reaction resemble human asthma, but the onset and subsidence are perhaps more rapid.

3. The pathologic picture in the lungs is characteristic and is similar in many respects to that seen in bronchial asthma in man.

4. Asthma induced by inhalation of histamine differs from experimental allergic asthma by a more abrupt onset as well as a more rapid disappearance of symptoms. It is, therefore, more difficult to control and measure. Its pathology is similar to allergic asthma but differs in degree.

5. Allergic asthma in guinea pigs is an excellent method for measuring the effect of agents on the reaction.

6. Active histaminase (3 units) given intravenously has no demonstrable effect on allergic asthma in guinea pigs.

7. Sensitization to histaminase may occur with production of anaphylactic shock upon reinjection after a suitable interval.

ENTERAL ABSORPTION OF POLLEN ANTIGEN

GEORGE E. ROCKWELL, M.A., M.D., CINCINNATI, OHIO

WITH the renewed interest in the use of oral pollen therapy the question of absorption has been argued pro and con. The experiments have varied with the investigator and his point of view.

Thommen¹ (1923) cited a patient with ragweed sensitivity to whom ragweed pollen was given orally. He demonstrated that the active antigen was present in the patient's blood and urine, a fact which he concludes is proof that it must have been absorbed. Black,² experimenting on himself, ragweed sensitive, found that the ragweed antigen was present in his blood, urine, and feces after the ingestion of the pollen extract. Each of these investigators employed sensitive patients, such as would naturally form the class of person presented to the physician for treatment, and administered daily doses to them.

Such was not the case in the experiments of several other investigators. Bernstein and Kirsner,³ Bernstein and Feinberg,⁴ London,⁵ and Zeller⁶ administered orally *single doses* of either ragweed pollen extract or whole ragweed pollen to *nonallergic* persons on whom local areas had previously been passively sensitized. They were unable by this method to demonstrate sufficient absorption to cause a reaction in the passively sensitized areas. Of this group of investigators, Zeller comments that by direct skin testing he was unable to demonstrate circulating pollen antigen following *either oral or hypodermic* administration of antigen. He, furthermore, admits that there were certain clinical symptoms following oral therapy which occurred with sufficient frequency that they could be accounted for only on the basis of enteral absorption.

Black, in discussing Zeller's⁶ paper, states that he believes the administration of a single dose of pollen extract, even though it is large, will show little or no absorption, since most of it is excreted by the bowel. However, he points out, continued administration over a period of time does give demonstrable amounts in the blood and serum. In pursuance of this phase of the discussion it is interesting to note the report of London.⁵ Contrary to the results of Thommen and Black, he was unable to demonstrate the presence of any rag-

weed antigen in sera collected from several of his experimental patients who had taken the pollen orally. Attention is called to the fact that he collected his sera the day after the ingestion of the pollen, whereas Thommen and Black collected theirs on the day of the ingestion. Black notes particularly that after twenty-four hours the concentration of pollen antigen in the sera was greatly reduced. I believe that the important factor is proper timing between the administration of the pollen antigen (either orally or hypodermically) and the sampling of the blood or tissues.

Alperstein⁷ (1940), reporting a study of patients sensitive to ragweed who had been placed on oral pollen therapy, comments that the experiments showed (a) that an appreciable amount of pollen is absorbed through the gastrointestinal tract, and (b) that reagin and allergen coexist in the circulating blood at the height of treatment.

Vaughan⁸ cites the experience of a physician in connection with a severe attack of asthma suffered by a ragweed-sensitive patient after eating the meat of a pheasant. It was known that the bird's craw had been full of ragweed seed. Accordingly, the physician tested the woman with extract of normal pheasant meat and then with an extract prepared from the meat of a pheasant whose craw was full of ragweed seed. To the former the patient reacted negatively, and to the latter she reacted positively. This suggested the following experiments which I herewith report.

*Twenty-four hours later the "½ hour serum" gave an inflammatory reaction 3 inches in diameter.

EXPERIMENTATION

Rabbits (either small or large) were given defatted ragweed pollen orally. Approximately two to two and one-half hours later they were killed. The kidneys, liver, and a piece of leg muscle were removed and quickly rinsed with tap water. Each was then ground and extracted with a solution consisting of 5 per cent glycerin in normal saline, 1 c.c. of extracting fluid being used for each gram of tissue. The tissues were allowed to extract in the icebox for

twenty-four to forty-eight hours, at the end of which time they were passed through a Seitz filter for sterility. Of the 19 rabbits used in the experiment, two were normal and furnished tissues for the control. To each of the other 17 1 Gm. of pollen was given orally.

Each of the extracts, together with a normal tissue extract control and a ragweed extract control, was tested on several ragweed-sensitive persons. Likewise, some of them were tested on a normal nonallergic person. All skin tests were done by intradermal method.

The results are given in Table I. A summary of the results showed that in ragweed-sensitive patients the control tissue extract gave a *negative to a two-plus wheal without pseudopodia*, while the extracts from the tissue of the rabbits which had been given the ragweed pollen orally, gave, in most cases, a *two-plus to a four-plus reaction with pseudopodia*. The control ragweed extract gave on the average a four-plus wheal with pseudopodia. These results were so definite that there can be no question that some of the pollen antigen was absorbed.

Blood was collected from some of the rabbits just before the oral administration of the pollen and at varying time periods afterward. The sera from these specimens were separated and then tested intradermally on pollen-sensitive patients. The results are shown in Table II and indicate that the active pollen antigen appears in appreciable quantities in the blood fifteen minutes after the oral administration of the pollen, but that by two and one-half hours its concentration is decreasing. For comparison one rabbit was given subcutaneously 60,000 Noon units of ragweed pollen extract while another was given orally 1 Gm. of timothy pollen. These results also are shown in Table II.

DISCUSSION

The evidence to date indicates overwhelmingly that the active pollen antigen is absorbed in appreciable amounts when given by the enteral method. This evidence consists of (1) reports in the literature of 1,409 hay fever cases which had been treated by oral pollen therapy with definite improvement in at least 944 cases; (2) demonstration that the active antigen can be found in the blood and tissue of the rabbit and in the blood and urine of man after oral administration of pollen; and (3) positive reactions following enteral ingestion of pollen. These reactions can be interpreted only on the basis of absorption. Even the opponents of the oral method speak of reactions, and it is obviously inconsistent to cite the occurrence of these while maintaining that no absorption takes place.

The only negative evidence is that enteral absorption of pollen antigen is insufficient to produce a reaction in the passively sensitized skin of nonallergic persons, whereas such a reaction is produced by hypodermic injection. However, if a tourniquet is placed above the point of injection, thus slowing down the rate of absorption of pollen extract, the same negative result is obtained in the latter case. Hence, it is probable that the rate of absorption of ingested pollen is too slow to induce the local speed of reaction necessary in the passive transfer tests. This is further evidence of the safety of oral pollen therapy.

SUMMARY

Experimental evidence is presented which shows that after the oral ingestion of pollen by rabbits the active pollen antigen appears in the blood and tissues, kidney, liver, and muscles.

AGE INCIDENCE OF POSITIVE TUBERCULIN REACTIONS (MANTOUX)*

FRANCES PASCHER, M.D., AND MARION B. SULZBERGER, M.D.
NEW YORK, N. Y.

WITH A STATISTICAL ANALYSIS BY
ALEXANDER S. WIENER, M.D., NEW YORK, N. Y.

THE intracutaneous test with old tuberculin Koch (Mantoux test) has been used by many workers since 1909 to determine the incidence and the distribution of tuberculous infection. It has been shown that in a given community the incidence of positive cutaneous reactions to tuberculin depends on the size of the population, whether urban or rural, the incidence of active tuberculous disease, and the living conditions, particularly with respect to hygienic standards and the degree of overcrowding.¹

It has also been shown that the percentage incidence of positive reactions to tuberculin and the age at which the tuberculin test becomes positive may be decidedly different for different cities, and for similar classes of people.² In Vienna³ in 1909 the incidence of positive tuberculin reactions, in individuals clinically free from active tuberculosis, was found to be very high among the poorer classes; one-half the children showed a positive reaction at 5 years of age; about 90 per cent at 10 years, and 94 per cent at puberty. In New York City the incidence was found to be considerably lower during the years 1921 to 1928 by Smith,⁴ and in 1934 in a survey made by one of us (F. P.).⁵ Table I illustrates the striking difference in age incidence of positive tuberculin re-

*From the Skin and Cancer Unit, New York Post-Graduate Medical School and Hospital, Columbia University.

Received for publication, November 30, 1940.

actions in comparable sections of the populations of Vienna and New York City. The somewhat higher incidence in Smith's series as compared with the group studied by one of us (F. P.) may be explained by the fact that Smith's group included cases of active tuberculosis.

TABLE I
COMPARISON OF AGE INCIDENCE OF POSITIVE TUBERCULIN REACTIONS

AGE	VIENNA 1909 (%)	NEW YORK CITY 1921-1928 (%)	NEW YORK CITY 1934 (%)
5	50	14.7	9.5
10	90	37	29.1
12-13	94	45.5	35.2

The incidence of positive tuberculin reactions may vary with changing conditions. In the same community the lapse of a decade or a few years may influence the statistics considerably.⁶ Chadwick and Zacks⁷ reported a reduction of 23 per cent in positive reactions among children of the same age groups between the years 1917 and 1926, coincidental with an intensive antituberculosis campaign. It is important, therefore, when interpreting results to take into consideration the year or the period during which a survey is made.

EXPERIMENTAL

We should like to report the results of our studies in the age incidence of positive tuberculin reactions carried out in a group of 362 persons, ranging in age from a few months to 80 years.

The persons in whom the tests were made were patients treated for various dermatoses at the Skin and Cancer Unit during the year 1939. The clientele of this clinic consists predominantly of white urbanites from the more crowded districts of New York City, whose economic status may be rated as poor or lower middle class. Patients suffering from any form of skin tuberculosis were excluded from the study.

Old tuberculin Koch, obtained from the Department of Health of the City of New York, was used, and the Mantoux technique was employed. The initial test dose was 0.02 mg. of O. T. (0.1 c.c. of 1:5,000 dilution). The patients were retested with 0.1 mg. of O. T. (0.1 c.c. of 1:1,000 dilution) and 1.0 mg. O. T. (0.1 c.c. of 1:100 dilution) if the first injections failed to elicit a reaction.

The test site was examined forty-eight hours later, and the reaction was graded as one plus to four plus, as recommended by the National Tuberculosis Association.⁸ The patients were then classed as belonging to four different groups, depending on the intensity of the reaction and the concentration required to elicit a reaction:

- I. Strongly positive—if a three-plus to four-plus reaction was elicited with 0.02 mg. O. T. Koch.
- II. Moderately strong positive—if a one-plus to two-plus reaction was elicited with 0.02 mg. O. T.
- III. Weakly positive—if either 0.1 mg. or 1.0 mg. O. T. was required to elicit a reaction.
- IV. Negative—if the patient failed to react to 1.0 mg. O. T.

RESULTS

In the age groups of the first two decades there was a gradual rise in the incidence of positive reactions to 33.3 per cent. Between the twentieth and twenty-ninth years the rise in the incidence of positive reactions was sharp, from 33.3 per cent to 90.9 per cent. After the thirtieth year the positive incidence remained fairly constant, varying between 90 per cent and 98 per cent.

TABLE II
FREQUENCIES OF POSITIVE TUBERCULIN REACTIONS AT VARIOUS AGES IN A
RANDOM SERIES OF 362 PERSONS

AGES	NUMBER OF PERSONS TESTED	NUMBER OF NEGATIVE REACTIONS	POSITIVE REACTIONS	
			NUMBER	PER CENT*
0-4	26	26	0	0
5-9	20	19	1	5.0 ± 3.2
10-14	25	18	7	28.0 ± 6.0
15-19	33	22	11	33.3 ± 6.0

*The figure following the ± sign represents the probable error of the observed frequency.

In Table II are listed the frequencies of positive tuberculin reactions among 362 persons at various ages, and in Fig. 1 these results are presented graphically. The observed differences in incidence of positive tuberculin reactions at varying ages are statistically significant. The probable error of an observed frequency is calculated from the formula:

$$\text{Probable Error} = 0.6745 \sqrt{\frac{p(1-p)}{N}}$$

where p is the observed frequency and N is the number of persons in the sample tested. This formula was applied to the frequencies obtained for positive tuberculin reactions in various age groups, the results being listed in the last column of Table I. As an example, the calculation for age group 25 to 29 is given:

$$\text{P.E.} = 0.6745 \sqrt{\frac{(0.909)(0.091)}{44}} = 0.029, \text{ or } 2.9 \text{ per cent.}$$

The formula is said to be accurate only for samples containing 30 or more persons, but for the sake of uniformity it was also used for age groups 0 to 4, 5 to 9, 10 to 14, and 60 to 80, each of which contained less than 30 persons. However, the error in doing this is not great, since the smallest group contained 19 persons.

The frequencies of positive tuberculin reactions in two different age groups can be compared by determining the differences between the two frequencies and then comparing this difference with its probable error. The probable error of a difference between two independent frequencies p_1 and p_2 is calculated by using the formula:

$$\text{P.E.}_{\text{Diff.}} = \sqrt{(\text{P.E.}_{p_1})^2 + (\text{P.E.}_{p_2})^2}$$

The odds that a particular difference is significant, that is, not purely accidental, is determined with the aid of Table III. The usual convention is to consider as significant any difference which is more than three times its probable error.

TABLE III

SIZE OF DIFFERENCE IN RELATION TO ITS PROBABLE ERROR	ODDS THAT DIFFERENCE IS SIGNIFICANT	
\pm P. E.	1	to 1
\pm 2 P. E.	3.6	to 1
\pm 3 P. E.	21	to 1
\pm 4 P. E.	140	to 1
\pm 5 P. E.	1,300	to 1
\pm 6 P. E.	19,200	to 1
\pm 7 P. E.	427,000	to 1
\pm 8 P. E.	14,703,000	to 1
\pm 9 P. E.	730,000,000	to 1
\pm 10 P. E.	65,000,000,000	to 1

As an example, let us compare the incidence of positive tuberculin reactions in age groups 10 to 14 and 20 to 24. Here $p_1 = 28.0$ per cent and $P.E.p_1 = 6.0$ per cent; $p_2 = 57.5$ per cent and $P.E.p_2 = 5.1$ per cent.

Therefore, $p_2 - p_1 = 29.5$ per cent and $P.E. (p_2 - p_1) = \sqrt{(0.06)^2 - (0.051)^2} = 0.081$, or 8.1 per cent.

Since $p_2 - p_1$ is more than three times its probable error, this difference is probably significant. How increasing the size of the samples helps to demonstrate differences among the age groups is illustrated by pooling together the results for ages 0 to 24 and comparing these with the observations made on persons more than 25 years old. Among 144 persons under 25 years old the incidence of positive tuberculin reactions was 29.2 ± 2.9 per cent; among 218 persons older than 25 years it was 94.0 ± 1.1 per cent. Accordingly, the difference between these two groups was 64.8 ± 3.1 per cent, so that this difference was more than twenty times its probable error!

DISCUSSION AND SUMMARY

We are of the opinion that the sharp rise in the incidence of positive tuberculin reactions during the third decade, from 33.3 per cent to 90.9 per cent, may be of clinical and epidemiologic significance.

It has generally been held that in urban communities the majority of persons are infected with tuberculosis by the time adolescence is reached. Our findings, and the recent studies of others, indicate that this may not be so. Smith⁴ reported a positive incidence of 45 per cent in persons from 10 to 15 years old; Drolet,⁹ 29 per cent; Dickey and Seitz,¹⁰ 37 per cent; Aronson and Nicholas,¹¹ 31.8 per cent. Soper and Amberson¹² state, "in this country at large, roughly speaking, 50 per cent of the white population under the age of twenty does not react to tuberculin."

If the tuberculin reaction is used as the criterion of past or present tuberculous infection, our results indicate that under present conditions in New York City the majority of persons are not infected until adult life. Long¹³ has shown, however, that the tuberculin test may fail to detect all healed pri-

mary tuberculosis because of the waning of cutaneous sensitivity that occurs with healing. One cannot assume, therefore, that the rise of positive tuberculin reactions during the third decade is due entirely to initial infection with tubercle bacilli. Superinfection or reinfection of sufficient magnitude to heighten tuberculin sensitivity, spontaneous fluctuation in sensitivity, or increase of sensitivity due to maturation or other factors, must also be considered as the possible *modus operandi* in some cases.⁹

Fig. 1.—Incidence of positive tuberculin reactions at various ages based on a study of a random series of 362 persons.

The report of the New York State Department of Health (Division of Tuberculosis) in the annual report of 1937¹⁴ confirms the clinical significance of our findings. The largest number of new cases of active tuberculous disease of all types was reported during the third decade. This finding is in striking conformity with the present demonstration of sharp increase in incidence of cutaneous tuberculin sensitivity in precisely this age group.

The limitations of the tuberculin test as a sole means of case finding have been pointed out by Plunkett,¹⁵ and we are aware that the tuberculin test is of questionable value as a means of establishing an epidemiologic index of tuberculous infections.¹⁶ Study of age incidence of positive tuberculin reactions may serve, however, to indicate the age groups in which an intensive search for new cases should be made.

Under the present conditions in New York City the results of quantitative tuberculin skin tests coincide with the clinical statistics, showing that for the appearance of active tuberculous disease, the third decade appears to be the most vulnerable age.

⁹There are many possible explanations for the 9 per cent drop in positive reactions in the seventh and eighth decades, but these cannot be entered into here.

THE QUESTION OF PROTECTION AGAINST HISTAMINE AND ANAPHYLACTIC SHOCK IN GUINEA PIGS BY HISTAMINASE*

ROLAND C. HAWES, B.S., GORDON A. ALLES, PH.D., AND HYMAN MILLER, M.D.
LOS ANGELES, CALIF.

THE *in vitro* inactivation of histamine by histaminase preparations is a slow process even under optimal conditions, as shown by Best and McHenry.^{1, 2} However, Karady and Browne³ found that histaminase preparations injected into etherized guinea pigs exerted a protective effect against lethal doses of histamine, and also against anaphylactic shock. They concluded that histaminase acts more rapidly *in vivo* than *in vitro*, and that their observations afforded experimental support for the reported therapeutic effectiveness of histaminase preparations against allergic responses in man.

Haag and Latz⁴ also performed experiments which they interpreted as indicating a protective effect of histaminase against anaphylactic shock. This interpretation is not well supported by their experimental results, since, when normal guinea pigs were used, 12 showed greater symptoms when shocked twelve hours after "protection" with a histaminase preparation than did the 14 similarly sensitized and shocked controls which were not given a protective injection. Haag and Latz ignored these animals and drew their conclusions

*From the Laboratories of Dr. George Piness and Dr. Hyman Miller, Los Angeles. Received for publication, December 2, 1940.

from the results of a similar test done with 29 animals which had survived a (negative) trial of the desensitizing action of multiple small doses of histaminase. Alternative explanations of the mechanism of the protective action suggested by this experiment would appear to be possible, in view of the facts that histaminase preparations contain antigenic hog proteins and that the "protective" injections were immediately followed by slight but definite symptoms suggestive of anaphylactic shock.

Our own trials of histaminase preparations in man for the treatment of allergic conditions⁵ and for the control of histamine or allergic skin reactions⁶ did not give any definite indication of *in vivo* activity or of therapeutic effect. It was, therefore, thought desirable to repeat the experiments reported by Karady and Browne.

With one exception, the observations of Karady and Browne did not include any control animals handled in the same way as those treated with histaminase (etherization and intrajugular injection). This exception consisted of three guinea pigs given heat-inactivated histaminase followed by histamine, and it was found that these died more quickly than the controls given histamine alone. Not only were these animals too few in number to serve as convincing procedure controls, but there is a possibility that heating may have produced toxic properties in the histaminase solution.

In order to simplify our technique, and to conserve our limited supply of histaminase, we compared the protective effect of histaminase solutions with control saline solutions, both solutions being injected intracardially into unanesthetized animals.

EXPERIMENTAL

A. Solutions and Procedures.

Saline. An 0.85 per cent sodium chloride solution containing 1:1,000,000 of phenylmercuric acetate as preservative.

Buffered Saline. A solution of sodium chloride, disodium phosphate, and monopotassium phosphate, having a pH 7.4, a ratio of sodium to potassium ion concentrations of 40:1, and an ionic strength equal to that of 0.85 per cent sodium chloride. Same preservative.

*Histaminase.** "Parenteral histaminase," a soluble powder, received in sealed glass ampoules. For Experiment I the contents of 42 one-unit ampoules were dissolved in 28 ml. of buffered saline about two hours before use. For Experiment II, Part 1, five one-unit ampoules and 20 two-unit ampoules were dissolved in 30 ml. of saline about two hours before use. For Experiment II, Part 2, 20 ten-unit ampoules of a special experimental lot were dissolved in 27 ml. of buffered saline three hours before use. After two guinea pigs had been killed immediately (with pulmonary and pleural hemorrhages) by intracardial injection of the last solution at the usual dose of 8 ml. per kilogram, it was diluted 1:5 with buffered saline in order to bring it to the same strength (in labeled units) as the other histaminase solutions.

*Histaminase was supplied through the courtesy of the Winthrop Chemical Co. and Dr. J. B. Rice, its Director of Medical Research. The one-unit ampoules were designated "T-360-1," and the two-unit ampoules, "T-360." Samples of these were returned to the manufacturers for re-assay just before Experiment II, Part 1, was done. They reported that the "T-360-1" had dropped in potency to about 60 per cent of the labeled value, while the "T-360" retained its original potency.

Histamine. A solution containing 10 mg. of histamine dihydrochloride (Hoffman-LaRoche) per milliliter in buffered saline was freshly prepared for each experiment in which it was used.

Egg Albumen. The stock from which solutions were made is a four times crystallized preparation,⁷ consisting of the washed crystal mush, pressed between blotters to remove most of the wash liquor, dried rapidly in a current of warm air, and stored in the cold. Nitrogen analyses showed that about 1.5 per cent of the egg albumen was denatured by drying, and that the total content of egg albumen was 64.2 per cent, while the content of ammonium sulfate was 31.7 per cent. For sensitization 46.7 mg. of the dry material was dissolved in 30 ml. of buffered saline (1 mg. of egg albumen per milliliter), and for shocking, 4.67 Gm. were dissolved in 30 ml. of buffered saline (100 mg. of egg albumen per milliliter).

Fig. 1.—Experiment I—Histamine shock.

Doses and Injection Technique. Because our guinea pigs differed in weight from those used by Karady and Browne, it seemed desirable to give the histaminase and histamine in proportion to weight. Doses of 8 ml. per kilogram of histaminase solution, and 2.5 ml. per kilogram (25 mg. per kilogram) of histamine dihydrochloride solution were selected as a fair approximation to the average dose used by them. In the first experiment, however, two guinea pigs

were given 15 mg. of histamine dihydrochloride per kilogram (group A), and one group of animals (group C) was given 2 ml. of histaminase solution without regard to weight.

Histamine solutions were injected intraperitoneally. Histaminase and control saline solutions were given intracardially, using a 1¼ inch, No. 22 gauge needle, and entering the chest through the diaphragm, inserting the needle along the left side of the xiphoid process. The solutions were injected slowly, testing for needle placement by drawing a drop or two of blood up into the syringe at the beginning and end of the injection. Judging by the color of the blood, almost all the injections were made into the left side of the heart. The animals withstood the injections very well, with the exception of the first guinea pig of Experiment I, group D. The histaminase or control saline solution was always administered fifteen minutes before the shocking injection.

Fig. 2.—Experiment II, Part 1—Histamine shock.

Group	"Protecting" Injection (Intracardial)	Shocking Injection (Intraperitoneal)
A	None	25 mg./kg. histamine dihydrochloride
B	8 ml./kg. saline	25 mg./kg. histamine dihydrochloride
C	8 ml./kg. histaminase*	25 mg./kg. histamine dihydrochloride
D	8 ml./kg. buffered saline	25 mg./kg. histamine dihydrochloride

(For symptom key, see Fig. 1.)

*This histaminase solution contained, according to re-assay, approximately 0.9 unit per milliliter, instead of the intended 1.5 units per milliliter.

The sensitizing and shocking doses of egg albumen were given without regard to animal weight, 1 ml. of the respective solution being administered intraperitoneally. The sensitizing dose was given two days after the animals were received, and the shocking dose was administered six weeks later. To assure ourselves that the ammonium sulfate content (49.4 mg. per milliliter) of the shocking solution was not high enough to be toxic, and that the solution was otherwise free of primary toxicity, three nonsensitized guinea pigs (group

E, consisting of three of the six survivors of Experiment II, Part 1, which was done fourteen days previously) were given the shocking dose of egg albumen solution. They showed no signs of difficulty or discomfort at any time.

Animals. All guinea pigs were obtained from a single source and were uniform in age. Those for Experiment I weighed from 480 to 650 Gm. Those for Experiment II, both parts, all obtained at one time, were all white, weighed from 200 to 250 Gm. when received, from 340 to 480 Gm. when Part 1 (histamine shock) was done four weeks later, and from 400 to 510 Gm. when Part 2 (anaphylactic shock) was completed. The animals were not selected for sex. A record of sex was kept for Experiment II, but no differences were seen. The guinea pigs were fed plenty of greens, supplemented by rabbit pellets, and water was available to them at all times.

Fig. 3.—Experiment II, Part 2.—Anaphylactic shock.

Group	"Protecting" Injection (Intracardial)	Shocking Injection (Intraperitoneal)
E	(Not sensitized, see text)	100 mg. egg albumen
F	None	100 mg. egg albumen
G	8 ml./kg. histaminase*	100 mg. egg albumen
H	8 ml./kg. buffered saline	100 mg. egg albumen

(For symptom key, see Fig. 1.)

*This histaminase solution contained 1.5 units per milliliter.

B. Experiments.

The results of the experiments are shown in the diagrams: Fig. 1 for Experiment I, Fig. 2 for Part 1 of Experiment II, and Fig. 3 for Part 2 of Experiment II. Each line represents a guinea pig, and the key to the symbols is shown in Fig. 1. The symptoms were classified as mild, moderate, and severe, in the order of their usual development, as follows:

Histamine shock symptoms:

Mild: depression, lowered respiratory rate, scratching.

Moderate: respiratory difficulty, coughing, gasping.

Severe: collapse, convulsions.

Anaphylactic shock symptoms:

Mild: restlessness, ruffled fur, sneezing, scratching, loss of sphincter control.

Moderate: irregular respiration, jumping.

Severe: rearing, gasping, collapse, convulsions.

(Depression is the principal symptom after dyspnea has disappeared, when animals show signs of recovering.)

All the animals which have been used by us in this type of experiment are included in the results.

DISCUSSION AND CONCLUSIONS

A slight prolongation of survival time after histamine by histaminase solutions occurred in both C and D of Experiment I, and a marked prolongation in anaphylactic shock in Experiment II, Part 2. To this extent our data agree with the findings of Karady and Browne.³ However, in no experiment was there any definite indication that the histaminase solution had greater efficacy than an equivalent volume of the saline solution used to dissolve the histaminase; and in Experiment I more of the saline solution group of animals survived than of the histaminase treated groups. However, none of the differences between any two groups of animals is statistically significant. Therefore, the only conclusion which may safely be drawn from the experiments is that Karady and Browne's statement that histaminase protects animals against histamine and anaphylactic shock is not supported either by the evidence they offered or by our findings. It should be pointed out that this cannot be taken as proof that histaminase preparations altogether lack in vivo activity of this nature, but only that the question remains undecided at present.

Because of the failure of any solution used in Experiment II, Part 1, to show protective action against histamine shock, we are unable to draw any definite conclusion regarding protective effect by saline injections. However, it is interesting to note that the dose of 8 ml. per kilogram is of the same relative order of magnitude as that used in intravenous saline therapy for surgical and other shock in man.

MELANOTIC RETICULAR HYPERPLASIA OF LYMPH NODES*

REPORT OF A CASE

LOUIS A. SOLOFF, M.D., PHILADELPHIA, PA.

BIOPSY, whenever possible, has become a routine procedure to establish a diagnosis which cannot be made with certainty by any other means. This is especially true in the difficult group of diseases characterized by lymph node enlargement. It is important to bear in mind that local lymph node enlargement may not necessarily have any relation to a systemic illness of which the patient complains. The purpose of this paper is to report a characteristic lymph node pattern which was found accidentally in a young adult who died of acute pulmonary military tuberculosis. This benign lesion has some superficial histologic resemblances to the malignant lymphoblastomatous and lymphogranulomatous lesions with which, indeed, it was confused until the true nature of the lesion was described by Pautrier and Woringer.¹ It is, therefore, worthwhile to call attention to this generally unfamiliar, although probably not uncommon, lesion.

REPORT OF CASE

K. T., a young negro boy, 17 years old, entered the Temple University Hospital on the service of Dr. Charles L. Brown on Sept. 14, 1940. He was well until June 1, 1940, when he noticed sharp stabbing pains around the heart, which lasted ten to fifteen minutes, and which were at times so severe as to cause him to faint. He was put to bed by his doctor for three weeks. At the expiration of this time he found that he was too weak to stand and was very short of breath. Three weeks before admission he developed pains in his extremities, especially the lower ones, and in his joints. Since the onset of his illness he lost 50 pounds. All during his illness he believes that he had fever, which occasionally was as high at 104° F.

Physical examination revealed a young adult negro male who had evidently lost considerable weight. There was nothing of note in the entire examination, except for the chest and inguinal lymph nodes. Expansion was limited and lagged on the left side of the chest. There was impaired percussion on the left side posteriorly from T₄ downward; this extended anteriorly to the midaxillary line. Breath sounds were absent in this region. There was moderate enlargement of the inguinal lymph nodes on both sides. These lymph nodes were discrete, not tender, and varied in size up to 5 cm. in diameter.

The laboratory findings were as follows: hemoglobin varied from 11.5 Gm. to 13 Gm. (Haden-Hausser significant). R.B.C. 4.01 to 4.83 million, W.B.C. 6,300 to 5,700. The average differential was neutrophils 74 (N. F. 47), lymphocytes 17, monocytes 6, eosinophile 1, neutrophilic myelocytes 3. Urine was slightly positive for occult blood, 6 to 7 R. B. C. per high-power field, W.B.C. 3 to 4 per high-power field occasional coarse granular casts. The electrocardiogram revealed a simple tachycardia with low T-waves, suggestive of some impairment to myocardial function, probably secondary to the patient's general infection. During his stay in the hospital he ran a continuous fever, ranging from 99° to 105° F. X-ray examination of the chest revealed an abnormal diffuse punctate type of density throughout both lung fields, and a small fluid collection in the left pleural space. Intravenous pyelogram presented a normal x-ray appearance.

*From the Department of Medicine, Temple University Medical School, Philadelphia.
Received for publication, November 30, 1940.

The presumptive diagnosis was tuberculosis. However, sputum, gastric washings, urine, and cerebral spinal fluid studies were repeatedly negative for tubercle bacilli. Because of the inability to establish a definite diagnosis, it was decided to remove one of the inguinal lymph nodes for histologic study.

The lymph node removed was pigmented and slate gray in color. It was completely encapsulated. In one section at one pole there was a single island of giant cells, suggestive of tuberculous origin. The remainder of the gland had none of the characteristics of tuberculosis. There was considerable thickening of the capsule. The follicles were small and poorly defined and had been replaced apparently by a tremendous hyperplasia of the reticulo-endothelial cells. These cells were polymorphous in appearance with occasional prominent and multiple nucleoli. The most striking feature, however, was the tremendous infiltration of fat and melanin within the reticulo-endothelial cells.

The patient died on Oct. 11, 1910, and autopsy disclosed an acute pulmonary miliary tuberculosis with terminal miliary spread to the other viscera.

Fig. 1.—Illustrating thickened capsule, disorganization of normal architecture, marked reticulum cell hyperplasia with deposition of fat and melanin.

DISCUSSION

The major portion of the lymph node picture was not obviously due to tuberculosis. The tremendous amount of fat, melanin, and reticular hyperplasia represented a puzzling picture until the contribution of Pautrier and Woringer was discovered. They found a rather characteristic histologic picture of lymph nodes in a variety of dermatologic diseases, the common denominator of which was pruritus. They called this lesion "La reticulose lipomelanique." The description of this lesion is taken rather freely from their contribution.

The lymph nodes are normally encapsulated and free of adhesions. They are moderately enlarged up to the size of a pigeon's egg. Upon sectioning, the cortical zones appear clearer than normal, with scattered brown flecks representing melanin deposits. Histologically, the lymph node tends to retain its fundamental architecture. The lymph follicles are smaller than normal and

are separated farther apart than normal. This is due to the interfollicular reticulum cell hyperplasia, which causes a gradual reduction and ultimate disappearance of the secondary lymph follicles. The germinal follicle, however, remains active and may be larger or smaller than normal, depending upon the extent of reticular hyperplasia. The reticular cells are predominantly cortical in position, although with increase in production, they may invade the medulla. The reticular cells are large pale cells with indefinite cytoplasmic borders. The cytoplasm appears faintly vacuolated with an empty meshwork. The nuclei are large, clear, elongated, or irregularly oval, with sprayed chromatin and occasionally two prominent nucleoli. These cells contain large quantities of lipoid substances easily stained with sudan III or scharlach R and are, according to

Fig. 2.—High power. Illustrating the polymorphous reticulum cell hyperplasia. The black deposits represent melanin. The clear spaces represent fat.

Pautrier and Woringer, cholesterol and double refractile. In addition, in the peripheral reticular cells especially are deposited large amounts of brown pigment, which by staining can be identified as melanin. The entire vascularity of the gland is increased. The marginal subcapsular sinuses are dilated and free for lymphocytic circulation. Eosinophiles may be found in them.

Pautrier and Woringer interpreted the hyperplastic proliferation of the reticular cells as due to an attempt of these cells to engulf and dispose of the excessive lipid substances and melanin. They found these lesions in persons subject to a variety of skin diseases associated with pruritus. Normally, melanin, which is elaborated by the melanoblasts in the basal layer of the skin is expelled toward the surface by the normal process of keratinization. A minute histologically undetectable quantity may travel toward the regional lymphatics and ultimately be excreted by the kidneys, and perhaps by the intestines. With scratching induced by itching, more than a normal quantity of melanin is formed. The regional lymphatics are dilated by the irritation. These factors, in addition to the massaging action of scratching, help to drive excessive quan-

ties into the regional lymphatics, where it is trapped by the reticular cells and causes them to multiply. They believe that the lipoid process is similar. The amount of melanin deposition varies with the duration and the severity of the skin lesion. It probably also varies with the melanin content of the skin.

In the absence of considerable melanin deposition, the lymph node may bear a striking resemblance to Hodgkin's disease. Dorothy Reed cells are not present, but the reticular cells are highly polymorphous and voluminous at times. The nucleoli are prominent and may be multiple; eosinophiles, plasma cells, and neutrophiles may be plentiful in the subcapsular lymphatics; fibrosis may be present in the older lesions, and a partial or complete disorganization of the lymph node architecture appears. Indeed, the diagnosis of Hodgkin's disease, mycosis fungoides, and reticulum cell sarcoma had been made on many tissues which Pautrier and Woringer later diagnosed as "La reticulose lipomelanique."

After histologic examination of the lymph node, the patient was asked specifically if he ever had any skin disorders. He stated that for several years he has had itching, occasionally scaling lesions in both groins for which numerous remedies had been tried unsuccessfully. These lesions were thought to be due to his occupation, which was that of pressing suits with a steam pressing machine. This required him to place one foot alternately on a foot stool. Apparently the heat and friction were sufficient to set up this irritation. He frequently attempted to obtain relief from the itching by scratching. He had been doing this work irregularly for the preceding four years and about two years before, he noticed the appearance of "lumps" in his groins.

CONCLUSION

A specific lymph node picture distinguished histologically by a marked reticulum cell hyperplasia rich in fat and melanin occurring in a variety of diseases characterized by itching is reported.

LABORATORY METHODS

GENERAL

THE OPSONOCYTOPHAGIC TEST IN ACUTE DIARRHEA IN INFANTS AND CHILDREN*

MERLIN L. COOPER, M.D., AND JANET P. MILLIKEN, M.S.
CINCINNATI, OHIO

FOR several years extensive bacteriologic studies have been made of the stools of infants and young children who were admitted to the Children's Hospital of Cincinnati suffering from acute diarrhea. Stools from 50 per cent of these patients have contained *Shigella paradysenteriae*¹ (dysentery bacilli), but repeated stool examinations have offered no information regarding the etiologic factor in the patients from whose stools *Shigella paradysenteriae* could not be isolated. It was hoped that a determination of the opsonocytophagic power of the blood of such patients for the organisms isolated from their stools might indicate a possible causal relationship between the presence of these organisms and the disease. This theory was not substantiated by observation in our group of patients—high indices being obtained from patients both with and without diarrhea. The results from the patients with dysentery, however, were of considerable interest and, accordingly, are being reported here.

METHODS

The method employed for studying the opsonocytophagic index was for the most part an adaptation of the method of Huddleson, Johnson, and Hamann,² and consisted of mixing equal quantities of citrated whole blood and standardized formalin-killed bacterial suspension in agglutination tubes, incubating for thirty minutes at 37° C., mixing, streaking as for a differential blood count, staining with dilute crystal violet, and determining the number of organisms in fifty polymorphonuclear leucocytes. Whole blood was used throughout these studies, because previous investigations by others^{3, 3} indicated that there is thus obtained a more accurate indication of the actual phagocytic response to bacterial invasion than when serum plus washed leucocytes of another individual or species is employed.

Sodium citrate was used as an anticoagulant, since, in our experience, heparin was not so satisfactory. Two and a half cubic centimeters of blood were added to small tubes containing 0.1 c.c. of a 20 per cent citrate solution in 0.9 per cent sodium chloride. The final concentration of citrate was 0.77 per cent. The specimens were kept in the refrigerator to prevent disintegration and were

*From the Children's Hospital Research Foundation, Cincinnati, Ohio, and the Department of Pediatrics, University of Cincinnati.
Received for publication, March 20, 1941.

used within four hours after they had been obtained from the patient. Specimens were thoroughly mixed just before using.

The formalized bacterial suspensions¹ were prepared by washing the growth from several twenty-four-hour-old brain agar slants with dilute formalin (0.4 c.c. of commercial formalin to 100 c.c. of a 0.9 per cent sodium chloride solution). After these suspensions of bacteria in formalin had been allowed to stand at room temperature for twenty-four hours, they were washed by centrifuging, decanting, and resuspending in fresh 0.9 per cent sodium chloride solution. This process was repeated three times. The density of the suspensions was standardized by the method of Gates,² so that a wire loop could be seen 2 cm. below the surface. Approximately 0.1 per cent formalin was added to the standardized suspensions as a preservative.

The phagocytic tests were set up in small, sterile agglutination tubes. The citrated whole blood (0.1 c.c.) and the formalized bacterial suspension (0.1 c.c.) were mixed by shaking the racks of tubes twenty times, after which they were placed in an incubator at 37° C. At the end of thirty minutes the tubes were removed, the contents were mixed by tapping gently twenty times, and the tubes were placed in an ice-water bath in order to check further phagocytosis. A small amount of the mixture was removed from each tube with a capillary pipette and smears were prepared as for a differential blood count. The best preparations were those on which the smear thinned out and terminated near, or just beyond, the center of the slides. It was found advisable to dry the smears rapidly by fanning at room temperature in order to avoid distortion of blood cells.

Most of the stains recommended by other workers did not appear to be satisfactory; some of them failed to stain the bacteria well, some stained the red cells too deeply, and others gave a hazy, indistinct appearance to the entire slide. Eventually, it was found that crystal violet gave excellent stains when used in the following manner: Smears were fixed momentarily in absolute methyl alcohol. While still dripping with alcohol, they were immersed in freshly prepared dilute crystal violet (1 drop of saturated alcoholic solution per cubic centimeter of distilled water) for approximately ten seconds. They were rinsed immediately in running tap water and dried rapidly in air. The bacteria stained deep purple; the white cells, lavender; and the red blood cells, bluish green.

Parenthetically, it may be noted that this method of determining opsonocytophagic power was satisfactory when used in the study of patients suffering from typhoid fever. The stained smears were examined by means of the oil-immersion lens. Most of the leucocytes were found along the sides and terminating edges of the smears. The number of phagocytized organisms in fifty polymorphonuclear leucocytes was noted and the average was then determined.

STUDY OF PATIENTS WITH ACUTE GASTRO-ENTERITIS

A number of different organisms were isolated from the stools of infants and children suffering from acute gastro-enteritis, in whose stools no members of the *Shigella* group were found. *Escherichia coli* were isolated from the stools of each of twelve patients; *Streptococcus faecalis* and organisms in the *Aerobacter*

group from approximately two-thirds of the patients; members of the *Salmonella* group from one-third of the patients; and members of the *Proteus* group from two patients. The phagocytic counts varied greatly for these organisms, and the high indices were distributed at random throughout the gastro-enteritis group and the control group without diarrhea. In none of these patients could any significance be attached to a high phagocytic index.

PATIENTS WITH DYSENTERY

If the phagocytic counts on the blood from ten patients whose stool cultures contained *Shigella paradysenteriae* are compared with those from a group of patients without dysentery, as in Table I, it is seen that the blood specimens from all the patients with dysentery tested gave increased counts with the *Shigella* antigens, whereas none of the blood specimens from the patients without diarrhea showed any increase. Counts above 0.5 were considered to be significantly increased. The blood was secured during the acute stage of the disease, except when otherwise noted in the tables. Variations in the opsonocytaphagic index on blood of the patients with dysentery are seen in Table II, showing the tendency to increase during the acute stage and to decrease with convalescence.

E. M.	16.3	5 days	28.1

STUDY OF A FAMILY WITH DYSENTERY

Interesting observations were made of the phagocytic counts obtained with blood from several children in one family, several members of whom had

dysentery (Table III). *Shigella paradysenteriae* of the Flexner type were isolated from the stools of four of these children, Elizabeth, Eugene, Florence, and Harriet, only the last of whom was severely ill. Two other siblings, George and Alice, also had diarrhea, but no *Shigella paradysenteriae* were isolated from their stools. The other sibling, Jennie, had no diarrhea, and no organisms of the *Shigella* group were found in her stools.

TABLE III
PHAGOCYtic STUDIES IN A FAMILY IN WHOM DYSENTERY DEVELOPED

PATIENT	DIARRHEA	STOOL CULTURE	SHIG. PARADYS-ENTERIAE (HARRIET)	E. COLI (FLORENCE)	E. COLI (HARRIET)	AEROBAC-TER AEROGENES (HARRIET)	STREP. FAECALIS (FLORENCE)

M. S.†	No	-	2.2	23.2	0.7	0.5	1.9

*Six months later.

†Infant with scalp infection.

The four siblings who had dysentery, and the two who had diarrhea with negative stool cultures, gave high phagocytic counts with the *Shigella paradysenteriae* recovered from Harriet's stool. Jennie, who did not have a diarrhea and whose stool culture was negative, showed no increase in her phagocytic count. In the lower part of Table II it is seen that the blood of the patients without diarrhea did not have an elevated index for the *Shigella paradysenteriae*, except in the instance of M. S., an infant with furunculosis of the scalp, whose index was only slightly above normal.

SUMMARY

The whole blood from patients suffering from acute infections with members of the *Shigella paradysenteriae* group gave increased opsonocytophagic counts with antigens of these organisms. Blood from patients without diarrhea did not give increased counts with such antigens.

Blood from patients suffering from infection with *Shigella paradysenteriae* and from those with diarrhea whose stools did not contain these organisms gave high phagocytic counts at times with various bacteria other than *Shigella* isolated from their stools.

These tests do not furnish evidence suggesting that any particular bacteria might be the causative agent in those children suffering from diarrhea whose stools are negative for the *Shigella* group.

The opsonocytophagic test aids in the diagnosis of infection with *Shigella paradysenteriae*, but it is not a necessary test when it has been demonstrated that the stools of patients contain these organisms. A negative opsonocytophagic test (counts less than 0.5) probably indicates the absence of dysentery infection.

A NEW METHOD OF STAINING WITH WRIGHT'S SOLUTION*

VICTORINO DE LA FUENTE, A.B., M.D.
MANILA, PHILIPPINES

THE primary requisite of a good method of staining is its capacity to reveal clearly the various structures in the blood film in order that they may be easily distinguished from one another. Simplicity, practicability, and rapidity may also be added as indispensable qualities for clinical purposes.

The method now suggested carries these features. It is as follows:

1. Cover the dry smear with a few drops of Wright's staining solution.
2. *With the breath* blow the smear as uniformly as possible until it becomes pinkish violet in color. This process will consume about ten seconds. The harder one blows, the faster will be the fixation of the stain.
3. Wash with tap water.
4. With the water running slowly over the slightly tilted slide, pour a few drops of Wright's stain. The contact between it and the smear should be made as short as possible. A long contact may decolorize the smear.
5. Wash, dry, and examine under oil immersion.

Two new features have been introduced: (1) the blowing of the smear with the breath, and (2) the washing of the stained smear with the staining solution itself. The first accelerates the process of staining, reducing its entire duration from minutes to seconds. The second dissolves the precipitated particles left in the course of staining. It thus solves one of the important objections to Wright's stain, i.e., precipitation of the solution on the slide.

Another decided advantage of this method is that in case the hematologist is not satisfied with the shade of color obtained at the first attempt, he may rectify it without much loss of time. If the smear is understained, he may repeat step 2; if overstained, step 4. It must be remembered that Wright's staining solution is a decolorizing as well as a coloring agent, depending upon the duration of its contact with the smear. This method renders the blood film

*From the San Juan de Dios Hospital, and the Department of Medicine, University of Santo Tomas, Manila.

Received for publication, November 16, 1940.

flexible in the hands of the examiner. The process of restraining and decolorizing may be repeated several times on the same smear without the slightest injury to the cells.

If a more thorough study of the red blood cells and the platelets is desired, the following procedure may be inserted between steps 3 and 4:

3a. Dry the film, put one drop of cedarwood oil over it. Add xylol to dissolve and with the palmar surface of the small finger cover the whole slide with the solution, in the same way as when cleaning a slide after use. Dry and proceed to step 4.

This modification, which turns the film pink in color, is useful also in the examination for malarial parasites and in counterstaining after brilliant cresyl blue. It deepens the contrast between the malarial bodies, or the "net" structures and the pinkish cytoplasmic background.

I have employed this method with good results in staining smears secured from the peripheral blood and the bone marrow. I have found that it has all the advantages of Wright's and Giemsa's stains minus their objectionable features.

SUMMARY

A new method of staining with Wright's solution is proposed. It is simple, very rapid, practical, and convenient. It does not leave precipitates on the slides and shows structures very distinctly. A modification of the same for the study of the erythrocytes, platelets, reticulocytes, and malarial parasites is also recommended.

A METHOD FOR STOMACH TUBING SMALL ANIMALS*

CHARLES S. MATTHEWS, M.A., EDWARD L. SCHWABE, M.A.,
AND FREDERICK E. EMERY, PH.D., BUFFALO, N. Y.

RECENTLY we were confronted with the problem of establishing a technique suitable for the prolonged oral treatment of a large number of rats. The procedures used by others seemed both unphysiologic and too time-consuming, and in addition entailed unnecessary risks. For example, a method necessitating the use of an anesthetic requires too much time and may have unphysiologic sequela. In our trials the use of a semirigid catheter as a stomach tube proved unsatisfactory, since the material was readily nicked by the teeth of the rat and the sharp edges of these cuts were obviously a source of irritation to the esophagus. The splendid results obtained by the method of Pugh and Tandy,¹ which employs a modified hypodermic needle, are indicative of a highly feasible method. Nevertheless, we wished to simulate more nearly the proved procedure employed for human work.

After trying these procedures with modifications, we finally developed a method which involves not only a minimal number of manipulations on the part of the operators, but also relatively little discomfort to the rat.

*From the Departments of Physiology and Materia Medica, University of Buffalo.
Received for publication, March 10, 1941.

During a period of six months some 200 animals of various ages have been subjected to this procedure for varying lengths of time, representing approximately 4,000 treatments without the loss of a single animal from trauma or drowning.

The procedure we have developed is easily and rapidly performed, and entails no deleterious effect to the animal.

Fig. 1.—Shows the instruments used for this method.

Fig. 2.—The esophagus of an animal treated by this method three times weekly for twelve weeks (enlarged 50 times).

Fig. 3.—The esophagus of an untreated animal (enlarged 50 times).

APPARATUS

In order to open the rat's mouth and at the same time have complete control of its jaws during the procedure, the forceps shown in Fig. 1 was developed. The instrument, called a needle nose pliers, may be procured from any automobile supply store for a nominal sum. The original spring attached between the handles was considered too stiff and was, therefore, removed. To develop the necessary tension rubber bands were substituted and wound around the blades just distal to the fulcrum. In this manner the amount of tension may be nicely adjusted to please the operator.

A No. 8 or 10 soft rubber catheter was employed as a stomach tube. A piece of adhesive tape wrapped several times around the catheter not only marks the distance it is to be passed, but also protects the tube at that point from the animal's teeth.

A large No. 12 gauge hypodermic needle, which snugly fits the catheter, was used to attach it to the syringe.

PROCEDURE

The procedure requires two operators, one to hold the animal and open its jaws with the forceps, and the other to pass the stomach tube and administer the medication.

The animal is held gently but firmly, its head projecting upward between the thumb and forefinger. Excessive motion is prevented by extending the remaining fingers along the belly of the rat. With the other hand the operator inserts the blades of the forceps between the jaws just behind the incisors and applies pressure sufficient to maintain the mouth in a suitable position for passage of the stomach tube. The other operator then proceeds to pass the tube by running its tip along the roof of the mouth to gain entrance into the esophagus, and with gentle pressure pushes it downward until the strip of adhesive tape is at the level of the incisor teeth.

One of the advantages of this method is that the operator is able to feel any abnormal resistance that the tube may encounter in its course and is thus able to prevent injury or death of the animal. If this condition occurs when about two-thirds the measured distance of the tube has been inserted, one may feel reasonably certain that the trachea has been entered. If, however, the hindrance is beyond this point, it is almost certain to be at the cardiac sphincter. In either case it is best to remove the tube entirely and to repeat the process after the animal has rested several minutes.

In order to ascertain whether, after a prolonged period of treatment by this method, any unwarrantable conditions developed, each esophagus and stomach was subjected to a careful examination. Some one hundred examinations showed no gross pathology. Subsequent histologic studies revealed only one case of a traumatic ulcer. The esophagus shown in Fig. 2 is typical of an animal treated three times weekly for twelve weeks. Fig. 3 shows the esophagus of an untreated animal.

THE MICROSEDIMENTATION RATE*

ROBERT S. HERZOG, M.D., CHICAGO, ILL.

THE usefulness of the sedimentation rate is well established in following the course of rheumatic fever and rheumatic heart disease. It has been widely studied in tuberculosis and in many other conditions. Interest in the test appears to be increasing, and the desirability of a clinically suitable micromethod would seem evident.

It is the very multiplicity of methods for the sedimentation rate that has probably kept this test from having the widespread clinical use that it deserves. Each method has required its own normal standards, and in the case of micromethods, these "normals" have often been inadequately derived, and unverified by others who have accepted them. This may explain why some authors consider that an adequate micromethod does not exist.

Recently, a monograph on sedimentation considered only venipuncture methods, and showed that the small diameter tubes of any micromethod would have a greater inaccuracy than the larger macrotubes.⁴ This need not prevent the use of the micromethod clinically, although it might well interfere with the study of the nature of the sedimentation phenomenon. Uneven settling of the column of red blood cells, probably the chief criticism against the use of the narrow microtubes, has rarely occurred in my studies. (Irregular settling, whether in large or small tubes, is sometimes due to reticulocytosis, as it has been shown that the reticulated red blood cells remain at the top of such unevenly settling columns.¹³)

Any method for sedimentation must provide for collection of blood with the use of an anticoagulant, adequate mixing, and suspension of the blood column in a strictly vertical position. As long as this required two to four or more pieces of glassware, and as many maneuvers, no method, micro or macro, was likely to get into widespread use in the office or clinic. Seven years ago Landau³ published his micromethod, which was simple to the point of encouraging frequent use. I have worked with it since 1934, and wish to report certain further simplifications (but not fundamental alterations) of the method, as well as the results of my clinical studies and the normal values established with its use.

Since this is not fundamentally a new method, the results are directly comparable with previous studies.^{3, 5} The results are not comparable with other methods unless the height of the blood column in the tube and the method of

*From the Adolescent Cardiac Clinic, the Medical Services, and the Cardio-Vascular Department of the Michael Reese Hospital.

Presented in part before the Chicago Society of Internal Medicine, March 27, 1939.

Received for publication, March 22, 1941.

TABLE I
COMPARISON OF PREVIOUSLY DESCRIBED MICROMETHODS

AUTHOR	YEAR	NORMALS	LENGTH OF BLOOD COLUMN	BORE OF TUBE	ANTI-COAGULANT
Landau ⁸	1933	1 to 8 mm. in 1 hour (174 tests on 78 children; 1 to 5 mm. in 70 men; 1 to 8 mm. in 80 women)	62.5 mm.	1.0 mm.	5% sodium citrate
Elghammer ³	1934	3 to 8 mm. in children		Landau's method	
Cutler ²	1927	2 to 8 mm. for men; 2 to 10 mm. for women. (Comparable to his macromethod, which also uses a 50 mm. blood column height; 5,000 patients were studied by the macromethod)	50.0 mm.	2.5 mm.	5% sodium citrate
McSweeney ⁹	1934	10 mm. or less for normal children and rheumatic children in a quiescent period	100.0 mm.	1.0 mm.	3.8% sodium citrate
Beaumont and Maycock ¹	1935	0.5 to 4 PER CENT in one-half hour for men, and 1 to 8 PER CENT for women	100.0 mm.	1.13 mm.	3.8% sodium citrate
Smith ¹²	1936	"Within the range usually stated by the Cutler venipuncture method for normal adults." Did 45 tests on 42 patients, but only 18 tests on patients 8 years old or over	50.0 mm.	2.5 mm.	5% sodium citrate
Rogatz ¹¹	1938	"All observers have found that a normal sedimentation value lies between 5 mm. in one-half hour and 10 mm. at the end of 1 hour." Reported only 7 tests on children 8 years old or over, and only 50 tests in all		Smith's method	
Vollmer ¹⁴	1939	8 to 10 mm. in 1 hour. Over 15 mm., "marked acceleration." Did 104 tests on 52 children	44.5 mm.	2.5 mm.	3% sodium citrate
Kato ^{6, 7}	1940	0 to 20 PER CENT	64 to 102 mm. (Whatever the tube dimensions, a VOLUME of 50 c.mm. of blood is constant)	0.79 to 1 mm.	Special potassium oxalate formula "approaches heparin results"

recording are the same (see Table I). The attempt to compare different methods by recording the millimeters of settling as percentages of the original blood column height is only approximately accurate, since changing the height of the original blood column does not necessarily change in like degree the observed sedimentation distance.

Landau reported his readings as *millimeters in one hour* (i.e., millimeters of fall of the top of the settling erythrocyte column). In my experience, this method is clinically adequate and preferable to other methods of reporting, such as millimeters per minute during the period of greatest fall, arbitrarily chosen index or percentage systems, or the time required to fall some given distance. A graph can be made of the rate of fall by five-, ten-, or fifteen-minute periods during the hour, but this is rarely useful, and certainly not conducive to doing many tests at one time, as in a clinic. Occasionally comparison of the thirty-minute value with the final reading appears to be useful.

The normal values previously established have been open to question. Landau's original material consisted of 78 children, admitted to the hospital for various causes, and found, after careful examination, to be without demonstrable symptoms of disease.⁸ On these patients 178 tests were done. Landau adds that "we had ample experience among polyclinic patients. The normal values for children over two years of age may vary from 1 to 8 mm. without any pathological condition being present. We have been unable to discover any noteworthy difference in value for different sexes with any degree of certainty. Our impression is, however, that as a general rule the normal values do not exceed 5 or 6 mm. But it is of great importance in such a phenomenon as sedimentation not to draw too narrow limits for the normal values." In 80 healthy women of the hospital staff he found values of 1 to 8 mm., and in 70 men, values of 1 to 5 mm.

The next year Elghammer,³ using Landau's method, stated that "values of 3 to 8 mm. are to be regarded as normal rates in children; 8 to 11 constitutes the zone of possible pathologic indication, 11 to 25 a definitely increased rate, and 25 to 50 a marked acceleration."

No subsequent studies by this method have appeared in the American or English literature. Seven other micromethods have been described, each with the fault either of needless complexity of technique, or of inadequately derived normal values, or both. These are summarized in Table I, along with Landau's and Elghammer's results.

In the present study with Landau's method, about 2,600 tests were available for analysis. Experience soon showed that acceptance of previous normal standards was causing confusion and apparent unreliability. An attempt was made, therefore, to derive normal standards, statistically, and in patients clinically verified to be normal as far as activity of rheumatic infection was concerned.

It is not my purpose to discuss the nature of the phenomenon of sedimentation, influence of various anticoagulants, the detailed comparison of micro-methods and macromethods, nor the question of the various so-called corrections. This has been well covered by others.^{4, 5, 12} Landau's method has been found useful clinically without considering any corrections other than that of room temperature. This should be between 60° and 80° F.; if the room is 5° to 10° F. above this, the reading may be 2 to 4 mm. higher; if the room is correspondingly below 60° F., the reading may be 2 to 4 mm. lower than the "true" reading (see also Appendix at end of paper). Fortunately, the present trend of

investigators is to realize that "corrections" may well favor incorrect clinical judgments. Hambleton and Christianson,⁵ and Kato,⁶ have stressed this in particular.

Of the 2,600 tests mentioned, which were the basis of this study, 2,094 tests were made on patients, from 8 to 23 years old, with cardiac involvement. The immediate purpose was to establish "normal values" for this group, so as to make of the test a useful indicator for judging the presence or absence of active rheumatic infection. The following were the criteria for selecting tests for statistical analysis of the normal range:

1. Absence of any clinical evidence of active rheumatic infection or carditis at the time of the test.
2. Absence of any type of infection or recognized disease, other than the inactive rheumatic fever, at the time of the test.
3. Absence of any suspicion of such rheumatic activity or other disease or illness within a month before and after the given test.

Fig. 1.—Distribution curve for determining normal values.

Tests not meeting these criteria were not included as a "normal" for statistical study even if they fell unquestionably within the normal range.

On the above basis, 1,165 tests were suitable for analysis, 620 on boys and 545 on girls. Of these, 352 were done personally; the remainder were done at the Sunset Camp for Cardiac Children by eight resident physicians under my supervision.* In many instances, the children were seen year after year, at the camp and in the various clinics in Chicago.

Fig. 1 shows the distribution curve of these 1,165 tests. It is seen to be skewed to the left, but it is reasonable to accept it as being within the limits of a normal distribution curve. In such a case the data from which the curve

*A special statistical study was made to demonstrate the fact that these residents learned the method quickly, and that their results were uniformly comparable and reliable.

is constructed may be used for the statistical derivation of a range of normal values. The basis for these statements is found in Table II, as well as the results of the statistical study. In a series of studies, one of the purposes of which was to establish normal values for a modified macrosedimentation method, Osgood and his associates¹⁰ have shown that their observed values for the sedimentation rate also follow a skew curve.

TABLE II

RESULTS OF A STATISTICAL ANALYSIS OF 1,165 MICROSEDIMENTATION TESTS FOR THE DETERMINATION OF NORMAL VALUES

	TOTAL	BOYS	GIRLS
Number of tests	1165	620	545
Range	1 to 33	1 to 33	1 to 27
Mean	8.52	7.80	9.33
Mode	5	5	10
Standard deviation	4.62	4.67	4.57
Average deviation	3.54	3.47	3.63
Standard deviation divided by average deviation*	1.31	1.34	1.26
Error of mean	± 0.14	± 0.19	± 0.20
Upper limit of normal	17.76	17.14	18.47
Upper limit of normal for practical purposes	18	18	18

*For a "normal curve," this quotient is usually considered to be 1.25 or less. The values here shown are trivially over the limit.

Inspection of Fig. 1 shows a range of one to 33 mm. in one hour. However, the upper limit of normal is not to be taken as 33 mm. The mean is 8.52 mm., and as seen in Table II, the standard deviation of the mean for all tests is 4.62 mm., with the standard error of the mean $0.19 \pm$. In other words, the mean really is somewhere between 8.33 mm. and 8.71 mm., and the average variation from the mean of any given test is 4.62 mm.

For practical purposes the range of normal values is usually considered to be two standard deviations in each direction from the mean, when such data is available and forms a curve whose degree of skewness is within the limits of a normal distribution curve. Hence, 2 times 4.62 (the two standard deviations) plus 8.52 (the mean) equals 17.76 mm. Since the test is read only to the nearest millimeter, it may be stated that 18 mm. in one hour is the upper limit of normal for all tests.

The lower limit becomes less than zero, which would mean, statistically, that there was no such thing as too slow a rate. Actually, this is not the case, as will be discussed subsequently.

Theoretically, 95 per cent of all the tests are included in this total range of four standard deviations. Actually it here includes 97.5 per cent. Although the half dozen or so "unexplained" high values are almost certainly artifacts, they are not excluded from analysis.

Reference to Table II again will show that the upper normal limit for girls is slightly higher than for boys, and this is true also of the mean values. These differences can be shown to be statistically significant, but practically they are unimportant, being scarcely more than a millimeter. As stated previously, the test is read only to the nearest millimeter.

Twenty-five per cent of these tests are higher than 10 mm., the previously accepted normal limit. In reviewing the records of *all* those patients in the 11 to 18 mm. group, it is found that, first, many patients with mild upper respiratory infections and various minor conditions have normal rates, that is, 18 mm. or less. It has been an aid to clinical thinking to regard these as normal rather than as "slightly elevated" rates.

Secondly, and more important, no one with a rate consistently 18 mm. or less had *active* rheumatic fever or carditis at the time of the tests. Seeming contradictions to this are rare. The most important exception is congestive heart failure following acute rheumatic carditis, when the rate may fall to normal levels (perhaps because of liver damage with consequent decrease in blood fibrinogen).

No further comment is necessary about the well-recognized high rates in the presence of acute rheumatic fever or carditis, nor the fact that the high rate may have some other explanation.

The finding of a rate of 1 mm. or less should suggest first a clot in the tube. In its absence, the possibilities of polycythemia, liver damage, and finally, an allergic state should be considered. I have observed for some years an adolescent girl with mitral stenosis and true bronchial asthma whose sedimentation is usually 4 to 10 mm. When she developed a mild acute polyarthritis and carditis, her rate rose to 16 mm., regarded as abnormal for her.

There is a great value to repeated tests on each patient, so that the normal or control values may be established. In this way the significance of changes may be better appreciated. Normally, the sedimentation rate does not change more than a millimeter or two from day to day or week to week. Furthermore, there are no variations after eating, exercise, or bathing, such as cause confusion at times in leucocyte counts.

Serial rates are especially important in judging control values in middle-aged and elderly patients, in whom the diagnosis of "normal health" is always an increasingly difficult matter, and normal standards for sedimentation are harder to define. Approximately an additional 500 tests were studied in these older patients. For the present it has been found useful to apply the same normals as for the younger patients.

In the case of the rheumatic patients, the most difficult decisions as to management often come in that group with clinically borderline or questionable activity of infection. Herein the test has had its greatest practical usefulness. I have not been led astray by using this higher upper normal limit. It has served as an aid in deciding that in some cases 99.2° F. was to be regarded as the normal mouth temperature; in others that a heart rate of 100 did not depend on active carditis; in still others that loss of weight and appetite were not indications of recurrent rheumatic infection.

It should be restated that these comments are valid *at the time of the test*. In fact, the finding of a normal rate aids in interpreting the events of the past week or weeks rather than in foretelling the future. A normal rate may rise to 35 or more several days after the onset of an acute infection. In my experience

an equally rapid fall from high levels has not been encountered; several weeks or more are required after the acute episode is clinically over; indeed, sometimes it is several months.

Conversely, the finding of an abnormally high rate must be taken seriously, and an effort should always be made to find the reason for it. Increased sedimentation is not usually the earliest evidence of active rheumatic infection, but it may be, especially in the case of recurrences. Other significant signs or symptoms will appear in a week or two, rarely as long as a month. A preceding upper respiratory infection may have been responsible for this apparent "earliest evidence," but all upper respiratory infections are not followed by rheumatic activity; hence the rate may return gradually to normal. However, rheumatic reactivations are by no means all preceded by upper respiratory infections, so that the clinical reason for the early increase of sedimentation (before fever or tachycardia appears) may not be readily explainable.

SUMMARY

In a study of nearly 2,100 microsedimentation tests by Landau's method on 405 patients with cardiac disease, ranging in age from 8 to 23 years, values have been derived which are normal for inactive rheumatic infection, and probably for the age group as well. The upper limit of normal is 18 mm. in one hour, although the mean is 8.5 mm., and 75 per cent of the tests are 10 mm. or less. The results fall within the limits of a normal skew curve, permitting statistical analysis.

The Landau micromethod is advocated because of its simplicity and the absence of need for applying corrections.

No contradictions have been encountered to the rule that a rate of 18 mm. or less eliminates active rheumatic infection or carditis at the time of the test, with rare and fairly well understood exceptions, the most important of which is congestive heart failure following acute carditis. Conversely, a high rate must always be taken seriously, even in the absence of other signs or symptoms, and an effort must be made to find the reason for the high rate.

The possible significance of very low rates is discussed.

Approximately an additional 500 tests were studied in patients without rheumatism and in middle and elderly age groups; in the latter the diagnosis of "normal health" is always an increasingly difficult matter, and normal standards for sedimentation are harder to define. For the present, it is found useful to apply the same normals as for the younger patients, with emphasis on the establishing of control values by serial testing of each patient.

APPENDIX

Technique for Sedimentation Test.—Prepare the finger as for a blood count; for this acetone is preferred. Insert the short end of the pipette into the rubber tip of the aspirating syringe. After the patient's finger has been stuck, draw 5 per cent sodium citrate solution into the tube to the lower mark (12.5 mm. from the tip), wipe off the excess from the outside, and insert the tip into the drop of blood on the finger. (The first, second, or third drop may be used, with or without squeezing; if the coagulation time happens to be rapid, the fourth drop may cause error.)

Draw the blood into the syringe by slowly unscrewing the plunger of the syringe; the blood mixes with the citrate as it is drawn up, and when the advancing column of fluid, regardless of whether it is blood, citrate, or blood-citrate mixture, reaches the second mark (50 mm. above the first mark), no more blood is drawn into the tube. Remove the pipette from the finger, draw the fluid column up several millimeters more, and then wipe off the tip of the pipette. It is easy and desirable to develop the practice of holding the assembled outfit of pipette and syringe in one hand during this phase of the procedure, during which the tube should be held nearly vertically.

Now mix the blood by drawing it into the bulb of the pipette so as to leave about 5 mm. still in the straight part of the tube, and then re-expel it. This is continued until the blood has been drawn into the bulb and expelled at least eight times. After the fourth time the tube may be rotated 180° about its long axis for subsequent mixings. During this time it is well to hold the tip of the assembled outfit somewhat lower than the syringe while the blood is being drawn into the bulb and re-expelled. This tends to prevent the formation of air bubbles in the blood. However, the fluidity of the blood is sometimes such that the tube must be kept nearly vertical at all times; otherwise the blood will be broken up in the bulb by air bubbles.

It is important to avoid handling the bulb with the fingers; to do so warms the air in the bulb. When the tube is finally set up at room temperature, the cooling of the bulb may draw the blood column partly back into the bulb. If this occurs, remixing is necessary. Occasionally one can manipulate the outfit to expel an air bubble which may have formed by holding the tip uppermost. If the blood column is intact for all but a millimeter or two at one end after final mixing, significant error does not result. Otherwise, or if more than one air bubble has appeared, the test may be "salvaged" by expelling all the blood into a small depression such as that of a hanging-drop glass slide, and then drawing it back slowly so as to exclude the bubbles. I wish to emphasize that in practice this salvaging maneuver is rarely necessary.

After these mixings, when the blood is in the straight part or bore of the tube, put a finger of the left hand tightly over the tip of the pipette, and slowly remove the syringe with an even, unscrewing motion. Remove the left finger and press a small ball of plasticine firmly against the upper end from which the syringe has just been removed. Turn the tube upright quickly and place it in the wooden block. This maneuver requires no more than twenty seconds after the mixing is stopped, and if as much as sixty seconds elapses, an error may be introduced. The time for setting up a test, from start to finish, need not be over one and one-half to two minutes.

When the blood is let into the bore of the tube for the final time, the apparatus is turned into a vertical position, and the blood is slowly expelled from the bulb, so that a minimal amount adheres to the walls of the bulb. The bottom of the column should be about 15 mm. from the tip—the exact point is immaterial. An accurate millimeter rule is used to measure the distance of settling.

One of the outstanding advantages of this technique is that the test can be set up at some later time (up to six hours) and can be readily transported, e.g., from patient's home to the office. In this event, after mixing and putting on the plasticine seal, one may carry the tube horizontally or nearly so. (A fountain pen box makes a useful container in the bag.) When it is subsequently to be set up, the following is the procedure:

Hold the tube horizontally. Remove the plasticine by drawing the fingers toward it along the outside of the tube from the bulb to the upper end; in this way, it is removed without squeezing any of the plasticine into the lumen. If the plasticine is unduly soft, the tube may be plugged in spite of precautions. In such a case, a fine wire may be inserted into the plugged end and the plasticine broken up sufficiently to permit use of the screw-suction syringe. This is an infrequent "complication."

When the plasticine is off, hold the tube horizontal, put a finger of the left hand firmly against the tip of the tube, and hold it there while the syringe is put on with an even screwing motion. There is now unequal pressure on the two ends of the blood column, which must be equalized before mixing. With the left finger still applied, unscrew the plunger of the

syringe about three-fourths turn, and remove the left finger cautiously, as though handling a volumetric pipette. If the blood column moves toward the tip, a little further unscrewing of the plunger is required, perhaps another one-quarter turn. If the blood column advances into the bulb, the plunger must be screwed in slightly. A little practice is required to do this without admixture of air bubbles or loss of blood, but the knack is quickly acquired.

Then proceed to mix as before, with this very important difference, that more mixing is required when the tube has been transported as already described. I have determined experimentally that 20 mixings in the bulb are not enough, and that 24 are usually sufficient. To be sure, then, mix the blood 32 times, eight times in each of the four quadrants of rotation about the long axis of the tube. This may sound like too many times, but it is accomplished in one and one-half minutes or less. When thus mixed, the tube is set in the wooden block, as previously described. I wish to stress again that the tube must be strictly vertical, and at a room temperature of 60° to 80° F. (A room temperature of 90° F. adds 2 to 4 mm. to the reading; the error is not constant, and depends upon what the original reading would have been; temperatures below 60° F. retard the fall by a like amount.) Furthermore, if the room temperature changes suddenly, for example, from 75° to 65° F. in a few minutes, the entire blood column will move in the tube. Error is thereby introduced, as settling cells tend to become mixed with the already clear plasma above the line of demarcation.

Materials.—Tubes of the Landau type and the "Gomco" screw-suction aspirating syringe are obtainable from commercial supply houses.*

A wooden block, approximately 2½ inches by 1 by ¾ inch, with holes machine-drilled in it so as to have them strictly vertical, will accommodate the tubes. Eight or ten holes can be drilled in such a block by any machine shop or carpenter. Most of the holes should be drilled with a No. 12 standard bit. To take care of chance odd sizes in the external diameter of the tubes, two holes can be drilled with a No. 11 bit, and two with a No. 13. A thin brass plate on the bottom will prevent uneven wear which may tend to throw the holes out of vertical alignment. (It has been shown that as little as 2 per cent deviation from the vertical will accelerate the settling in the tube, and thereby introduce error.¹⁵) A small pocket-sized spirit level may be used to check the levelness of the table or whatever support is used for the block.

A small package of plasticine or modeling clay, and 5 per cent sodium citrate solution, complete the outfit.

The somewhat more elaborate apparatus originally described by Landau was imported, and so far as is known is not now obtainable because of war conditions. I have used the original outfit, but I find it no more accurate, and indeed, less convenient. It was, furthermore, very expensive, which is not the case with the assembled apparatus herein described.

Acknowledgment is made to the Sunset Camp for Cardiac Children for studies made there.

SIMPLE, SHIELDED BIPOLAR ELECTRODES²

BRADFORD CANNON, M.D., AND ELIZABETH M. BRIGHT, A.B.
BOSTON, MASS.

IN 1933 one of us (B. C.), working in this Laboratory, described a method for stimulating autonomic nerves in the unanesthetized animal by means of implanted electrodes.¹ Because of their flexibility these electrodes were able to withstand the strain of being imbedded in moving parts for a considerable period of time, and, because soft rubber was used throughout, there was no injury to the nerve or adjacent tissue. During the intervening years a bipolar modification of these electrodes has been developed for use in acute experiments. They can be easily and inexpensively made, and are adaptable to nerves of various diameters and situations. In constructing the electrodes, which are shown diagrammatically in Fig. 1, the following directions should be followed:

1. Attach eight 10 feet lengths of No. 32 enameled copper wire to the end of the shaft of a motor and revolve the shaft until the wire is evenly and closely twisted. The result is a very flexible conductor. This will be called the "flexible wire" (*F*). It should be cut into lengths of one foot.

2. Make loops (*A*) of soft silver wire (No. 27), about 2 to 3 mm. in diameter, to fit inside a No. 12 French catheter, a size generally useful. Leave about 1 cm. of the wire extending from the loop; to this extension wind and solder one end of the flexible wire (*F*) from which the enamel has been scraped. This soldering should be done before the loop is put into the catheter, otherwise the rubber will be damaged by the heat.

3. Cut a length of the catheter slightly greater than the desired distance between the electrodes and split it longitudinally. Make two holes (*B, B*) with a cutting needle, each one 2 mm. from the end of the tube and 2 mm. from the split edge. Carefully insert through the holes the silver loops and tie each of them in place with heavy silk (*C, C'*). Coat each wire, near its emergence from the catheter, with a good quality of rubber cement, and then slip over it a 3-inch

piece of fine white stitch tubing (*D*, bore $\frac{1}{32}$, wall $\frac{1}{64}$ inch) pushing it firmly against the catheter. In the figure this tubing is not shown covering the nearer wire.

4. After the two emergent wires have been thus prepared and covered with the stitch tubing, tie them together in the covered portion. Coat the tubing and the outer surface of the split piece of catheter with rubber cement. Beginning with the free edge of the piece of catheter, near *C'C'*, wrap over it a strip of finest dental rubber dam, and continue the wrapping around the stitch tubing. Thus the end connections are insulated and short circuits are rendered impossible.

Fig. 1.—Diagram of shielded electrodes. *A, A*, silver wires; *B, B*, holes in the catheter; *C, C'*, silk ties to hold silver wire loops in place; *D*, rubber tube covering junction of silver wire and twisted flexible wire (*F*) (tube not represented over nearer junction); *E*, rubber tube covering junction of solid wire with twisted flexible wire (*F*).

5. Slip over each flexible wire (*F*) a 1-inch length of very small bore gray rubber tubing. To the scraped free ends of these wires solder a short piece of solid copper wire and then slide the rubber tubing back to cover the junction (*E*). This solid wire will serve as a connection to an induction coil.

TECHNICAL FACTORS INFLUENCING THE WELTMANN SERUM COAGULATION REACTION*

FRTZ B. SCHWEINBURG, M.D.,† AND LLOYD ROBERTS EVANS, M.D.‡
BOSTON, MASS.

IN 1930 Weltmann described a serum coagulation reaction taking place in dilute calcium chloride solution, which he used as the basis of a nonspecific laboratory test for the presence of certain general pathologic processes. The test has been accepted widely in Europe and to an increasing extent in this country. There have been numerous reports of its value in following the course and therapy of various diseases, including rheumatic fever. Comparisons between the serum coagulation reaction and the sedimentation rate as guides to the treatment of the rheumatic fever patient have been made, and it was such a problem that first attracted our attention. While performing many Weltmann tests certain technical sources of error were found, and since these have not been mentioned previously, we wish to report them, together with means for their elimination.

The method of testing serum coagulability has been well described by Weltmann¹ and Teufl,² and their directions were followed in performing and interpreting the reactions. Accordingly, we made up a stock solution of calcium chloride anhydrous, reagent Merck, a form of the salt containing at least 96 per cent calcium chloride. This solution was diluted further with distilled water to the concentrations necessary for the reaction. We then tested several normal sera with these dilutions but found that instead of a normal coagulation band (C. B.) of 6 or 6.5, they all gave bands of 8 and 9, or even 10. All workers agree that a coagulation band greater than 6.5 or rarely 7 indicates the presence of a proliferative or fibrotic process, while one less than 6 indicates an inflammatory or necrotic lesion. Triple distillation of the water failed to correct this, and in order to have less calcium chloride in our solutions we deviated from the directions by using calcium chloride dihydrate, USP XI, which contained 75.49 per cent of the anhydrous salt. Again we found the coagulation band of normal persons to be 7 or 8, and occasionally 9. In order to have even weaker solutions we then employed calcium chloride hexahydrate, reagent Merck, as described in a later paper by Weltmann and Sieder,³ and a recent one by Levinson and Klein.⁴ Of this preparation only 50.66 per cent is the pure salt. Even these weaker solutions produced coagulation bands of 7, 8, and 9 when normal sera were used. We never secured a normal coagulation band of 6 with any of these calcium chloride solutions.

*From the House of the Good Samaritan, Boston, Mass.

‡Former House Officer, House of Good Samaritan, Boston.

Received for publication, April 1, 1941.

Testing the acidity of the electrolytic solutions by the colorimetric method, we found them to be between pH 6.3 and 6.5, which was the same as that of our distilled water. Because Weltmann¹ had said that his solutions were alkaline, and Levinson and Klein⁴ had found theirs to be between pH 7.5 and 7.73, we adjusted ours to 7.6, with 0.1 normal sodium hydroxide. This was done by adjusting the distilled water to pH 7.6 prior to preparing the solutions to avoid their subsequent dilution. This was not a significant addition of cations, since Weltmann¹ found that the monovalent sodium did not react in the same way as the bivalent calcium. With our solutions adjusted in this way we tested a large number of normal sera and found each of them to have a coagulation band of 6 or 6.5.

Fig. 1.—Behavior of coagulation bands of six normal sera at different pH values.

Accordingly, we studied in more detail the influence of the pH upon the coagulation of the serum. We found that as the solutions became more acid, the coagulation band was higher or shifted to the right; and as they became more alkaline, it was decreased or shifted to the left. When this phenomena was examined more closely, we found all normal sera reacted similarly in the pH range from 7.2 to 7.8, by giving a coagulation band of 6, or rarely 6.5. In more acid or more alkaline calcium chloride solutions normal sera did not always give the same coagulation band; for example, at pH 8.6 normal sera had coagulation bands from 0 to 3, and at pH 5.6 most coagulation bands ranged from 8 to 10. In some sera, however, the coagulation band would first shift to the right as the testing solutions became more acid; but when a pH of about 5.8 or less was reached, the coagulation band became 0. In these cases no observable change took place in the tubes, not even a clouding of the fluid. This led us to believe there probably had been some change in the coagulable protein. These effects of the pH were

found regardless of the strength of the calcium chloride salt used to prepare our testing solutions. For instance, with the dihydrate of the salt, a pH of 8.4 to 9.0 was necessary before normal serum gave a coagulation band of 6, and in less alkaline solutions the band was higher. Fig. 1 records the coagulation band of 6 normal sera tested with calcium chloride solutions of different acidity and alkalinity. Many others tested gave similar results.

The only references to the hydrogen-ion concentration in connection with the Weltmann test, which we could find, were those of Weltmann,¹ Levinson and Klein,⁴ and Dees.⁵ Weltmann¹ said that his solutions were alkaline; this may have been due to the alkalinity of the water in Vienna, a fact known to one of us (F. S.) during previous work. Levinson and Klein⁴ mentioned the pH of their solutions but believed it had no effect on the coagulation band. In the same paper they report the influence of the serum pH on the reaction, pointing out that a decrease of the pH caused the coagulation band to shift to the right, while an increase caused the reverse to take place. This fact became more evident when their studies were repeated on the same patient. Despite this, they believed that there was no essential relationship between the pH and the coagulation band. Since we found the alkalinity of the testing solutions influenced the coagulation band, we felt that because the serum was diluted fifty times by these solutions, the pH of the mixture would be more nearly that of the larger volume of fluid. In other words, the pH of 5 c.c. of these solutions was not changed enough by the addition of 0.1 c.c. of serum to influence the reaction.

TABLE I

	<i>Amount CaCl₂ Solution c.c.</i>	<i>pH CaCl₂ Solution</i>	<i>Amount Serum c.c.</i>	<i>pH Serum</i>	<i>pH Mixture</i>
1.	2.5	9.0	0.05	7.6	8.6
2.	2.5	8.6	0.05	7.6	8.4

4.	2.5	7.6	0.05	7.6	7.6
5.	2.5	6.2	0.05	7.6	6.8
6.	2.5	5.8	0.05	7.6	6.3
7.	2.5	5.2	0.05	7.6	5.8
	<i>Amount CaCl₂ Solution c.c.</i>	<i>pH CaCl₂ Solution</i>	<i>Distilled H₂O c.c.</i>	<i>pH H₂O</i>	<i>pH Mixture</i>
1.	5	8.4	0.1	7.6	8.3
2.	5	8.0	0.1	7.6	7.9
3.	5	7.6	0.1	7.6	7.6
4.	5	7.0	0.1	7.6	7.1
5.	5	6.7	0.1	7.6	6.8
6.	5	6.1	0.1	7.6	6.2
7.	5	5.6	0.1	7.6	5.8

Dees⁵ found that the pH of the calcium chloride solutions was variable and ranged between 5.25 and 6.30, but that when the serum was added the pH of the mixture became 7.2 to 7.4 in every case. She concluded that this was due to the buffering action of the serum, and that, for this reason, the acidity of the testing solutions was unimportant. In an attempt to repeat this, we adjusted the pH of our solutions and tested the influence of the serum on them at the various adjusted values, but failed to secure a strong buffering effect. That

there is slight buffering action is shown when water of the pH of the serum is added to the testing solutions in the same amount as serum, but this is not strong enough to bring the mixture to the favorable range if the solutions are very acid or alkaline. Many sera were tested in this way, and examples of our findings are shown in tabular form in Table I.

An incidental finding was that if our solutions were exposed to the air for any length of time before the test was made they became more acid, and consequently the bands shifted to the right. This was probably because of absorption of carbon dioxide from the atmosphere. Probably for the same reason the reagents became more acid daily, and, for this reason, the pH was tested and if necessary readjusted each time they were used. Because of this change we found it advisable to test a serum of known coagulation band when pathologic sera were tested, as well as whenever fresh solutions were made. This control need not be human serum but may be normal rabbit or sheep serum, which usually have a coagulation band of 6, but occasionally 5 or 7. In this connection it should be mentioned that Hennes and Kemen⁶ advise making up fresh solutions every time the test is performed. This may have been due to the same unfavorable factors that influenced our reactions.

TABLE II

<i>Material</i>	<i>Coagulation Band</i>
Normal beaten rabbit plasma	5
Normal beaten rabbit plasma + oxalate	5
Normal human serum	6
Normal human serum + oxalate	6

Weltmann,¹ Teuff,² and Kaiser⁷ always used fresh serum, and Levinson⁸ said it was best to use fresh serum, but that it might be stored for as long as four days in the cold. We found that serum which was kept sterile and refrigerated gave the same coagulation band weekly for four and five weeks' time. Knowledge of this was valuable if for any reason we wanted to retest a serum.

We found that the reading of the test should be made immediately after the tubes were removed from the boiling water bath. If they were allowed to stand for any length of time, tubes which were densely cloudy without coagulation when removed from the bath, later showed a precipitate which might have been confused with coagulation. Hence tubes which should have been called negative would then be read falsely as positive, the coagulation band would be shifted to the right, and be greater than if the tubes were read at once.

Weltmann and Medvei⁹ found that when they tested plasma of blood defibrinated by agitation with glass beads, the coagulation band was the same as that of the serum. In our experience plasma of blood treated in this way had a coagulation band that was shifted one or two tubes to the right of the serum value. It must be considered, however, that plasma treated in this way is slightly hemolytic, even though the agitation with the beads is done as carefully and as gently as possible. It is generally known that hemolysis increases the coagulation band. Plasma of blood treated with a mixture of potassium and ammonium oxalate usually had a coagulation band one or two less than the serum. Occa-

sionally it was the same as the serum, and very rarely it was slightly higher. That this was not due to the addition of oxalate (the mixture which has been used contains 3 Gm. of ammonium oxalate and 2 Gm. of potassium oxalate in 100 c.c. of distilled water; 0.08 c.c. has been used for 2 c.c. of serum) could be seen when oxalate was added to serum or beaten plasma, and the mixture was tested one hour later showing no change in the coagulation band (Table II).

SUMMARY AND CONCLUSIONS

The importance of using the hexahydrate of calcium chloride for solutions employed in the Weltmann test has been re-emphasized. The pH of these solutions was found to be an important factor influencing serum coagulation, and the favorable range for this coagulation is between pH 7.2 and 7.8, with an optimum value of pH 7.6. Since the buffering action of the serum used in the test is not great enough to secure favorable values, the reagents must be adjusted to the suggested range.

If such adjustment is made, the pH of the solutions should be determined every time before use, and a control serum of known value should be tested with unknown pathologic ones. This may be the serum of a suitable laboratory animal.

Serum tested need not be fresh if it has been kept sterile and refrigerated after collection.

The test should be read immediately after the tubes are removed from the boiling water bath to avoid a false positive interpretation.

AUSCULTATORY BLOOD PRESSURE METHODS FOR DOGS*

FREDERICK M. ALLEN, M.D., NEW YORK, N. Y.

THE best blood pressure method accepted today for hypertension experiments in dogs seems to be that of subcutaneous arterial puncture,¹ which gives accurate pressures with little disturbance of the animal, and in expert hands permits fairly frequent repetition. However, when it is desired to make numerous daily estimations continued during many days or weeks, some indirect method is necessary. Aside from the antiquated van Leersum carotid loop, the choice is between oscillometry, palpation, and auscultation. The need for comprehensive serial pressure readings prompted me² to devise the first auscultatory method for dogs as one of the preparatory steps for the contemplated renal-vascular research in 1923. The consensus of trials by various workers³ has credited it with a reasonable degree of accuracy. Assuming, for argument, that errors may occur even greater than those reported, possibly to the extent of 10 or 15 mm. deviation from the true intra-arterial pressure, the general conclusion remains that direct methods may be used for precise acute experiments or for occasional checks on the indirect readings. For chronic experiments the frequently repeated readings by the convenient auscultatory method give a better picture of the general condition than a smaller number of technically exact determinations, which are subject to the far greater variations in the animal from hour to hour or from day to day. The reasons which make auscultation the preferred method for man may hold also for the dog.

Valuable criticisms and suggestions were made by Ferris and Hynes⁴ in 1931. Upon finding an opportunity to resume this work recently, I have attempted a further improvement, which is illustrated in Fig. 1. The dog with very little training learns to lie quietly on his right side, and the pressure is taken in the left thigh. The hair is preferably, but not necessarily, clipped. The adapter, molded in hot water from dental gutta percha, is slightly curved to fit the posterior margin of the thigh. This appears to be an advantageous innovation as compared with former devices fitted to the external surface, because there is so little variation in the posterior margin that the one simple adapter will serve for most kinds and sizes of dogs. The adapter is thin above and thick below to compensate for the taper of the thigh. The surface is slightly roughened, and there are flanges above and below between which a 4 inch cuff can be held securely. Instead of a harness attachment to the body, a cord passes to a weight hanging over the edge of the table, heavy enough to assure that the adapter and cuff cannot slip downward.

Readings on the femoral artery are taken by means of a stethoscope with a flat bell slipped slightly under the lower margin of the cuff. There is a

*From the Department of Physiology, New York Medical College, New York City.
Received for publication, April 30, 1941.

Fig. 1.—Adapter in position on posterior margin of left thigh, ready for application of cuff.

Fig. 2.—Dog lying on right side; left foreleg grasped with forefinger above olecranon; cuff applied above it.

possible advantage if the thick lower edge of the adapter spares the stethoscope slightly from too tight pressure under the cuff. If the bell piece is inserted too high, fictitiously high readings are obtained, just as when too narrow a cuff is used. Some practice is needed for the best wrapping of the cuff and accuracy of readings. Fairly large dogs are preferred, but readings have been obtained in Scotch and fox terriers. The feasibility of smaller equipment for still smaller dogs has not been investigated.

Sounds are audible in surprisingly small arteries, and I have confirmed the observation of Corcoran and Page⁵ that in some large dogs readings are possible in the *dorsalis pedis* with a 2 inch cuff above the ankle. But, since attempts have been made for several generations to find a satisfactory method for the cylindrical foreleg of the dog, it was a surprise to learn finally that brachial artery readings are practically as simple and as distinct as in man. As shown in Fig. 2, the animal's left elbow is held straight by the left hand with the forefinger keeping a continuous grip above the olecranon. A 2 inch cuff is applied around the humerus above this forefinger. The cuff is thus kept high enough until the stethoscope is applied below (outside) it, at or slightly above the elbow joint. The difference from the femoral readings is similar to that between the human arm and thigh. Both systolic and diastolic sounds are usually so sharp and clear that this method may be favored over the more complicated femoral method. The systolic fluctuations are not as wide as in the femoral. In both, the diastolic may resemble that in man, or there may be either low or high readings of which the cause or significance is unknown. The method for both limbs, however, is quick and easy, and each can serve as a check on the other.*

Shivering, panting, etc. may interfere seriously. Satisfactory sounds may be unobtainable in some states of anesthesia, hypotension, or weakness. The method, therefore, is not adapted to all types of experiments. For our hypertension studies, however, the numerous convenient combinations of systolic and diastolic, femoral and brachial readings have appeared more valuable than occasional mean pressures in a single artery.

SUMMARY

Convenient auscultatory methods are described for estimations of femoral and brachial blood pressures in dogs. Some advantages and limitations for different types of experiments are indicated.

THE LAUGHLEN TEST FOR SYPHILIS*

AN EVALUATION BASED ON COMPARISON WITH 3,100 HINTON TESTS

C. TRUMAN NELSON, A.M., D.M.D., BOSTON, MASS.

IN 1935 Laughlen¹ described a flocculation test for syphilis which employs a special modification of the Kahn antigen. Among the advantages claimed for this test were simplicity of performance, speed, accuracy, and ease of reading the results. Essentially, the antigen for the Laughlen test is prepared from the Kahn antigen by the addition of cholesterol, scarlet R dye, and balsam. The dye, which is insoluble in water, colors the lipid particles of the antigen but does not color the liquid in which they are suspended. Thus, when flocculation occurs after mixing a drop of antigen with a drop of the serum to be tested on a glass slide, the clumped particles become visible to the naked eye and the reaction is, theoretically, easy to read. The directions for the preparation of the Laughlen antigen are outlined in the original report. Preparation of the antigen is somewhat complicated and considerable experience is necessary to adjust it to the proper sensitivity. Since 1937, however, a uniform and stable "Laughlen reagent," in its inactive form, has been produced by the Lederle Laboratories, and the antigen for the tests reported here was obtained from that source. Activated antigen for performing the test is prepared from the inactive material by the addition of 10 per cent sodium chloride. The exact amount of 10 per cent sodium chloride necessary to activate 1 c.c. is marked on each lot of antigen. Inactive antigen is stable for approximately six weeks, but the activated Laughlen reagent will keep for seven days only, after which it becomes super-sensitive. The antigen must be activated twenty-four hours prior to its use; it has been our practice to activate antigen once a week in a quantity sufficient to last seven days so that it is always available for use. Ordinarily, 1 c.c. of antigen suffices for about 75 tests.

In his first communication Laughlen,¹ reporting on 400 routine blood specimens, found that his test showed 99 per cent agreement with the Kahn test, and 98 per cent agreement with the Wassermann test. These findings were

*From the Department of Bacteriology, Harvard University Medical and Dental Schools, Boston.

Received for publication, May 6, 1941.

confirmed in general by Robinson and Stroud,² and Price.³ The former investigators, in 1,000 routine tests on hospital patients, found 97 per cent agreement with the Kahn test and 93 per cent agreement with the Wassermann test. Later, Laughlen⁴ studied more than 5,000 specimens according to his method and reported an agreement of 98 per cent with the Wassermann test, and 99.4 per cent with the Kahn test.

Originally, Laughlen⁴ stated that his test could be performed successfully on spinal fluid as well as on fresh noninactivated blood samples. It is now generally agreed, however, that this is not so, and the pamphlet which accompanies the Lederle "Laughlen reagent" at present warns against using this test on unheated blood samples and spinal fluid. Furthermore, all the above-mentioned investigators,¹⁻⁴ recommended the Laughlen test for use in the doctor's office by physicians, and even by those who had no special training in serology. These unfortunate statements, however, have been retracted, and in recent months there have been no further exaggerated claims for the Laughlen test.

Since 1938 a number of reports on the Laughlen reaction have appeared in the literature. Several investigators have found the Laughlen test to be satisfactory under laboratory conditions, while other workers have thoroughly condemned the method. Muether and Greutter,⁵ after studying 1,000 blood specimens, concluded that the Laughlen test "is somewhat less accurate" than the Kahn test but "compares fairly well" with the Kline test. Dienst and Sander-son⁶ examined the blood sera of 276 known syphilitic patients, who had positive clinical manifestations of the disease, and found that the Laughlen test had a sensitivity of 96.3 per cent compared to 93.4 per cent for the Kahn test, and 77.8 per cent for the Kolmer-Wassermann test. At the same time these authors tested 687 presumably negative sera and found only one false positive reaction. Breazeale, Greene, and Harding⁷ performed the Kahn, Eagle, Ide, Kline, and Laughlen tests on 1,000 sera and showed an agreement between the tests of 98.4 to 99.5 per cent. Craig and Callaway⁸ examined the unheated sera from 1,000 patients and found that the Laughlen test agreed with the Wassermann test in 91.8 per cent of the cases. With the Kahn test, however, a 99.8 per cent agreement was obtained. In 1939 a comprehensive study of the Laughlen test was published by Beck.⁹ She found, in comparing the Laughlen test with 1,000 Kline tests, 1,100 Kolmer-Wassermann tests, and 100 Kahn tests, that the Laughlen reaction was just as specific (99.3 per cent) and somewhat more sensitive (77 per cent) than the other tests. Price¹⁰ reported that the Kahn and Laughlen tests detect treated syphilitic persons better than the Wassermann test. He also found that the Laughlen and Kahn tests remain positive longer than the Wassermann test in cases of treated syphilis. Recently, another valuable survey of the Laughlen test was completed by Lever and Massie.¹¹ They performed Laughlen tests on the sera of more than 2,200 persons and compared their findings with the results of the Hinton and Wassermann tests. They found that in 442 presumably syphilitic patients the Laughlen test had a sensitivity of 75.6 per cent compared with 97.5 per cent for the Hinton test, and 42.8 per cent for the Wassermann test. In 1,778 nonsyphilitic patients these workers found only 0.7 per cent false positive Laughlen reactions. Lever and Massie

also reported that the Laughlen test is less sensitive but more specific than the rapid Hinton test, and less specific but more sensitive than the Kahn test. Tashner¹² compared the results of the Kline, Kahn, and Laughlen tests on 1,500 blood samples and found that the specificity of the Kahn and Kline tests was approximately 99.6 per cent, while that of the Laughlen test was 98.6 per cent. He, therefore, concluded that the Laughlen reaction is somewhat less specific than the Kahn and Kline tests.

On the other hand, a number of investigators have been unable to confirm the above-mentioned favorable findings. Usher¹³ reported that the specificity of the Laughlen test is considerably less than that of the Eagle flocculation test. Furthermore, Usher found that when the sensitivity of the Laughlen reagent is reduced sufficiently to eliminate false positive reactions, it fails in a significant number of instances to detect sera giving a positive reaction with the Eagle test. Rein and Hazay¹⁴ found the Laughlen reaction less specific and less sensitive than the Kline test. Flood and Mayer¹⁵ examined 314 nonsyphilitic blood specimens and obtained four false positive reactions with the Laughlen test, whereas the Kahn, Kline, and Kolmer-Wassermann tests each gave three false positive results. On the basis of this small series, Flood and Mayer came to the statistically doubtful conclusion that the Laughlen test is less specific than the other three. These authors also found that the Laughlen test becomes negative earlier than the Kline, Kahn, and Kolmer-Wassermann tests during antisyphilitic treatment, and that the Laughlen test detects less early syphilis and less untreated syphilis than the other three tests. More recently, Moore¹⁶ compared the Laughlen test with the Kolmer-Wassermann and Kahn tests and found the Laughlen reaction to be too erroneous to justify recommendation. Churg and Sobel¹⁷ attempted to evaluate the Laughlen test by studying the reaction under conditions comparable to those in a physician's office or in a small laboratory. These authors compared their results with more than 2,000 routine Wassermann tests performed on the same specimens by the Serologic Laboratory of the City of New York. They found the Wassermann test to be more sensitive and more specific than the Laughlen test. In addition to these divergent results, editorial comments^{18, 19} have appeared which warn against the use of the Laughlen reaction by untrained persons.

Thus, there seems to be no general agreement in the literature concerning the value and effectiveness of the Laughlen test. This is unfortunate, since a rapid, accurate, and easily performed test for syphilis would obviously find many uses at the present time. Such a test, if it were sufficiently sensitive and specific, would be valuable in emergency transfusions under both war-time and peacetime conditions, in certain preoperative situations, and for the legally required premarital serologic tests now common in many states. In the light of these considerations, and because of the conflicting reports in the literature, it was felt that it might prove useful to re-evaluate the Laughlen test by comparing it with the Hinton test in a large series of cases. The latter test, as it is performed in Hinton's laboratory, is undoubtedly one of the best flocculation tests for syphilis available at the present time.^{20, 21} For the purpose of this study, 3,100 sera furnished by the Massachusetts State Laboratory were tested by Laughlen's method over a period of five months, and the results were compared with those

obtained in that laboratory by the Hinton reaction. Of these, 305 specimens were from proved syphilitic patients, almost all of whom had undergone various amounts and kinds of treatment. A total of 1,094 blood samples were from persons who had no clinical evidences or history of syphilis, and these are designated as "presumably negative." The remaining 1,701 sera were from persons whose medical history is unknown so far as syphilitic infection is concerned.

RESULTS

Of the 3,100 inactivated blood sera tested in this series, the results of the Laughlin test agreed with those of the Hinton test in 2,873 instances—an absolute agreement of 92.8 per cent. Of these, 609 were positive agreements, 2,256 were negative agreements, and 8 gave doubtful readings in both tests. Total disagreements numbered 227. These are analyzed in Table I.

TABLE I

227 CASES IN WHICH THE LAUGHLIN AND HINTON TESTS DISAGREED

Laughlin	+	0	+	?	0	?
Hinton	0	+	?	+	?	0
	64	70	21	13	22	37

Such data are not entirely satisfactory, since the actual sensitivity and specificity of the Laughlin test remain undetermined. There were 305 patients in this series, however, who had clinical manifestations of syphilis and whose blood sera showed a positive Hinton test. All but one of these had received some form of antisypilitic treatment at some stage of the disease, and 198, or 65 per cent, were patients with neurosyphilis. In this group of 305 inactivated syphilitic specimens the Laughlin test gave 247 positive, 56 negative, and two doubtful readings, or a sensitivity of 81 per cent. This figure approximates the results obtained by Beck,⁹ and Lever and Massie,¹¹ but falls far short of the sensitivity quoted by Dienst and Sanderson.⁶

To determine the specificity of the Laughlin reagent there were available 1,094 patients who had never had clinical manifestations or history of syphilis, and whose blood specimens yielded a negative Hinton test. In this series of presumably nonsyphilitic inactivated blood samples, the Laughlin test showed 1,077 negative, 12 positive, and five doubtful reactions, or a specificity of 98.4 per cent. This specificity is somewhat less than that quoted for the Laughlin test by other investigators,^{6, 9, 11, 15} and no obvious explanation for this could be found. It should be mentioned, however, that two false positive results were from patients who are now known to have had active tuberculosis at the time the specimens were obtained. Parran and Emerson²² have reported that false doubtful and false positive serologic tests are often encountered in persons with active tuberculosis.

Recently, Kirk and Bennett²³ described a rapid technique for testing small amounts of capillary blood with the Laughlin reagent. This method employs *noninactivated* blood samples, and although it has been generally conceded that the Laughlin reaction is thoroughly unreliable when used to test *noninactivated* sera, these authors found that the Laughlin test, performed by their method,

yielded entirely satisfactory results. In an effort to repeat the work of Kirk and Bennett, 577 blood samples were tested by the Laughlen reaction, using both heated and unheated sera. The results were then compared with those obtained with the Hinton test in the Massachusetts State Laboratory. In this series, when inactivated sera were used, the Laughlen test agreed with the Hinton test in 529, or 91.6 per cent, of the cases. Of these, 52 were positive agreements, 476 were negative agreements, and in one instance both tests gave doubtful results. This total absolute agreement does not differ significantly from that obtained in the entire series of 3,100 tests. There were 48 disagreements. These are set forth in Table II.

TABLE II

48 INACTIVATED BLOOD SERA WHICH YIELDED DIVERGENT LAUGHLEN AND HINTON TESTS

Laughlen Hinton	+	0	-	?	0	?
	0	-	-	-	-	-
	12	20	3	2	4	7

On the other hand, when the sera in this group were Laughlen tested without previous inactivation, the results agreed with the Hinton test in only 492 instances—an agreement of 85.2 per cent. There were 34 positive, 456 negative, and two doubtful agreements. The 85 disagreements are analyzed in Table III.

TABLE III

85 NONINACTIVATED BLOOD SERA WHICH YIELDED DIVERGENT LAUGHLEN AND HINTON TESTS

Laughlen Hinton	+	0	-	?	0	?
	0	-	-	-	-	-
	23	38	3	2	3	16

These results indicate that the absolute agreement between the Laughlen and Hinton tests is considerably less when the Laughlen reaction is performed with unheated blood sera. Heretofore it has been reported¹⁷ that it is the sensitivity of the Laughlen test which is decreased when noninactivated blood samples are employed. From Tables II and III, however, it seems that both the specificity and the sensitivity of the Laughlen reaction are seriously affected when unheated blood sera are used for the test. In addition, the difficulty of reading the Laughlen results is markedly increased when the test is carried out with noninactivated blood. This is suggested by the increased number of doubtful Laughlen readings in Table III.

In an attempt to determine further the effect of noninactivated blood sera on the specificity and sensitivity of the Laughlen test, blood samples were obtained from 31 known syphilitic patients and 350 presumably nonsyphilitic patients. These sera were then Laughlen tested before and after inactivation by heating at 56° C. for thirty minutes. The known syphilitic samples were Hinton tests. Presumably nonsyphilitic sera were from persons who showed no clinical evidences of syphilis and whose inactivated blood sera gave a negative Hinton test. In the small group of 31 known syphilitic blood samples the Laughlen test, performed on inactivated sera, showed 26 positive, five negative,

and no doubtful readings, or a sensitivity of 80.7 per cent. When the same syphilitic sera were Laughlen tested without previous inactivation, however, there were 19 positive, one doubtful, and 11 negative results, a sensitivity of only 61.2 per cent. In the series of 350 presumably nonsyphilitic blood specimens, the Laughlen test, after inactivation of the sera, yielded 343 negative, four positive, and three doubtful results for a specificity of 98 per cent. When the identical blood samples were tested by the Laughlen reaction, using unheated sera, there were 328 negative, nine positive, and thirteen doubtful readings for a specificity of 92.7 per cent.

The foregoing results reaffirm the conclusion that an attempt to develop a more rapid Laughlen technique by using unheated blood sera for testing is dangerous. Not only are the sensitivity and specificity of the test diminished, but the reaction is more difficult to read accurately when noninactivated sera are used.

COMMENT

The Laughlen test, possibly because of the exaggerated claims originally made for it, has not attained widespread clinical application up to the present time. The test is rapid and not particularly difficult to interpret, providing the observer has had sufficient experience. The antigen, as it is now supplied, is uniformly stable, and the preparation of the active antigen from the inactive material is relatively simple. Although the antigen must be activated at least twenty-four hours before use and although the active antigen is stable for only seven days, it is easy to prepare a week's supply of the reagent at one time. Such considerations would seem to make the Laughlen test particularly valuable for emergencies and for use in smaller outlying or isolated institutions, where it may be inconvenient or too expensive to perform other recognized tests for syphilis. Despite any claims to the contrary, however, considerable experience is necessary to read the Laughlen test accurately. In addition, the Laughlen test cannot safely be used to test spinal fluid or noninactivated blood serum.

From the confusing reports found in the literature, one cannot decide whether or not the accuracy of the Laughlen test justifies its acceptance. In general, it may be said that most of the evaluations which merely compare the percentage agreement of the Laughlen test with other well-known tests for syphilis on routine blood samples, are essentially unenlightening. A much more significant evaluation of any test for syphilis can be obtained by testing a series of known syphilitic and known nonsyphilitic blood samples, and expressing the results directly in terms of sensitivity and specificity.

In this study the Laughlen test performed on inactivated blood sera had an indicated sensitivity of 81 per cent, and a specificity of 98.4 per cent. This compares with a 77 per cent sensitivity and 99.3 per cent specificity obtained by Beck,⁹ and a 75.6 per cent sensitivity and 99.3 per cent specificity reported by Lever and Massie.¹¹ From these results it seems that the Laughlen test is considerably less sensitive than the Kline and Hinton tests and approximately as sensitive as the Kahn test.²⁰ The specificity reported in this series is definitely less than that found by Beck, and Lever and Massie. Ordinarily, an acceptable

serologic test for syphilis must maintain a specificity of at least 99 per cent—a figure which the Laughlen test did not attain in our hands.

By its nature the chief attraction of the Laughlen test probably lies in its ability to exclude quickly the possibility of syphilis in certain clinical emergencies and diagnostic dilemmas. But the fact that the Laughlen test has an apparent sensitivity of only 75 to 80 per cent seriously detracts from its value in just those situations in which it should be most useful. On the other hand, if the Laughlen antigen is used in a supersensitive state, or if the results of the test are read closely enough to detect 95 to 100 per cent of syphilitic sera, then the specificity of the reaction falls markedly.⁹ Nevertheless, the accuracy of the relatively simple Laughlen test is such that it may find a useful role in emergency situations, although its value in this respect probably does not equal that of the rapid Hinton test.¹¹ Greey, Bracken, and Paul¹² have recently indicated that the Laughlen test is a satisfactory method for detection of syphilis in blood donors, provided the serum is inactivated before testing. These authors also emphasize that the Laughlen reaction should always be confirmed by methods of greater specificity before a final diagnosis of syphilis is made.

If, as Dienst and Sanderson report,⁹ the Laughlen test is 96.3 per cent sensitive and 99.9 per cent specific, then it probably is the best test for syphilis now available. No other investigators, however, have obtained results approximating these. On the other hand, to condemn the specificity of the Laughlen test as Flood and Mayer¹³ have done on the basis that it showed four false positives whereas the Kahn, Kline, and Kolmer tests yielded only three false positives in 314 cases, is statistically unreasonable. The truth of the situation probably lies somewhere between these extreme viewpoints.

CONCLUSIONS

The Laughlen test is rapid and, in general, is approximately as easy to read as most acceptable flocculation tests for syphilis.

Of a total of 3,100 inactivated blood sera tested in this series, the results of the Laughlen reaction agreed with those of the Hinton test in 92.8 per cent of the cases. The sensitivity of the Laughlen test in 305 syphilitic patients was 81 per cent, and its specificity was 98.4 per cent in 1,094 nonsyphilitic persons.

The Laughlen test is thoroughly unreliable when used to test noninactivated blood sera. Not only is the sensitivity of the test markedly reduced, but its specificity is adversely affected, and the results of the test are more difficult to read.

I am grateful to Miss Genevieve Stuart and the Massachusetts State Laboratory for furnishing the blood specimens and for permission to compare results with those of the Hinton test. I am also indebted to Miss Louise M. Heaton and the Lederle Laboratories, Inc., for a regular and dependable supply of Laughlen antigen.

AUTOMATIC PIPETTE WASHER AND RINSER

ETHAN ALLAN BROWN,* M.R.C.S., LONDON, L.R.C.P., ENGLAND
AND NORBERT BENOTTI,† B.S., M.S., BOSTON, MASS.

WE HAVE in this laboratory devised a pipette washer. This instrument, almost entirely automatic, requires less than three minutes of attention each day. By its use glassware can easily be made chemically clean. The instrument also saves some of the costs of cleaning fluid, water, and breakage. Since the full advantages of such an instrument may not be fully obvious, it may be of value to review, if only briefly, both the necessity for clean glassware and the methods by which chemical cleanliness may be obtained.

By definition glass is chemically clean when its surface is so free of extraneous matter that a film of water distributes itself over the surface of the glass in a layer, monomolecular in thickness. When a pipette is dirty, drop-

†The Asthma Research Foundation, Boston.
Received for publication, May 8, 1941.

lets, however small, remain attached to its surface. A dirty pipette will, therefore, not drain within its limits of error. In a micropipette the error may exceed 10 per cent. Since all chemistry, routine or research, is based upon quantitative analysis, it is absolutely necessary that all pipettes be chemically clean. So high a standard of cleanliness is not really difficult to achieve. All that is needed is a good cleaning fluid and an efficient rinsing system.

Chromic acid is the best cleaning fluid available. It is not, however, always made by the proper methods nor is it handled with the proper care. To make it cheaply and to handle it so that it may be efficient for as long as possible, the following technique should be used:

Five grams of technical potassium bichromate should be dissolved in a minimum amount of water. To this concentrated aqueous solution of potassium bichromate should be added one liter of technical sulfuric acid. Any amount may be made as long as the proportions given are followed. The final solution is dark brown, and in it may be seen the suspended red chromic anhydride crystals. The chromic anhydride is the oxidizing agent. When reduced, it turns to the green chromic oxide and is then useless for cleansing purposes and must, therefore, be discarded. The oxidizing capacity is destroyed by reducing agents, especially organic solvents as alcohol and acetone. All glassware should be rinsed before being placed in the chromic acid solution. The sulfuric acid is hygroscopic, and the solution will absorb atmospheric water unless the cylinder in which it is contained is closed to the atmosphere by a glass plate. Heat is produced when the acids are mixed. They may be mixed with safety if the cylinder is made of pyrex glass.

With the usual method of washing pipettes, each pipette is taken in turn from the acid solution. One end is connected to a suction apparatus, and the pipette is rinsed in running water. Since water is used for both the suction and the cleaning, and since each pipette is handled individually, the process is noisy, tedious, and wasteful. Some breakage is inevitable.

With the instrument described below, any number of pipettes can be cleaned, and yet no individual pipette is handled from the time it is soiled until it is again clean, dry, and ready for use. The system can run at night and, in all, requires less than three minutes of attention for any batch of pipettes. No breakage is possible during the cleansing process.

The complete apparatus consists of two glass cylinders, both made of pyrex and both of the same size; and a third smaller glass cylinder which sits upright in either of the other two. Since the smaller cylinder (marked B) is the most important part of the apparatus, it is described first.

During the working day cylinder B stands or lies on its side on the laboratory bench; as the pipettes are soiled, they are placed in it with their tips upward. The base of cylinder B is in the form of a hemisphere so that the mouth-piece of each pipette stands at a tangent. The passage of the water or cleansing fluid is completely free.

When it is necessary to clean the pipettes, cylinder B is lowered into cylinder A. Cylinder A is so constructed that there is an inlet of small caliber and a siphon outlet of large caliber. When the water is turned on, it fills both cylinders, its level rising until the bend of the top of the siphon is reached.

Both cylinders then empty, since the rate of outflow is faster than the inflow. That arm of the siphon which is inside cylinder A is grooved at its lower end so that when the water falls to this level, the air breaks the flow through the siphon. As soon as this occurs, both cylinders begin to fill again. Each filling and emptying requires between five and seven minutes so that it is possible to obtain ten or more washings per hour.

With the inlet of cylinder A attached to tap water, the pipettes are rinsed and drained, and the material so removed helps to preserve the cleaning fluid.

Fig. 1.

After three or more such flushings (the number is not of importance since the process is automatic) cylinder B is lifted free of cylinder A and allowed to drain, or else the siphon is permitted to empty both cylinders and the water is turned off. Cylinder B is then transferred to the chromic acid bath, cylinder C. The pipettes are usually permitted to stand in this acid for ten to twelve hours or overnight. When it is necessary to remove them, cylinder B is now raised by means of a lead handle, and the acid drains back into cylinder C. Cylinder B is now placed in cylinder A, the flow of tap water adjusted and the apparatus again permitted to fill and empty automatically. After the rinsing procedure

has continued for a sufficient time, the pipettes may be rinsed in distilled water by changing the connection at the inlet of cylinder A. A double connection, one for tap and the other for distilled water, may be used. Cylinder B may then be removed and placed in a drying oven. A glass plate may be used for covering cylinder B, which can then be permitted to remain on the laboratory bench. The pipettes will drain and dry, and, if time is not a factor, no gas oven is necessary. The height of the siphon can, of course, be adjusted so that short pipettes may be washed without the necessity of filling cylinder A to the top, saving, therefore, both tap and distilled water.

By the procedures outlined as used with the apparatus described, pipettes can be made chemically clean. The procedure requires only a simple technique which avoids breakage, saves time, and lowers laboratory expense, since it uses less tap water, distilled water, and cleansing fluid than any of the present methods. The pipettes rendered chemically clean by this method make quantitative analyses much more accurate.

CHEMICAL

THE RELATIVE STABILITY AND POTENCY OF THROMBOPLASTINS FOR PROTHROMBIN TESTS*

HENRY G. PONCHER, M.D., JEANNETTE C. RICEWASSER, M.S., AND
KATSUJI KATO, M.D., CHICAGO, ILL.

IN OUR preliminary report¹ we stated that thromboplastin solutions prepared from dried rabbit brain are remarkably stable. This finding is contrary to Quick's² statement, for we have observed that saline solutions of dried rabbit brain retain their potency for as long as six months. However, the duration of the thromboplastic potency of these solutions varies decidedly according to the method employed in preparing the original brain powder used in making the suspensions. In order to test the relative potencies of thromboplastins, and to ascertain the duration of their activities, the dried brain powders were prepared according to the two most commonly used procedures, namely: (1) the acetone-dehydration method of Quick, and (2) the incubator-desiccation method of Magath.³

EXPERIMENTAL

This investigation, conducted over a period of six months following the initial preparation of one composite of rabbit brains, consisted of 14 series of observations at biweekly intervals (Table I). The potency of each thromboplastic reagent prepared throughout this study was ascertained by determining its prothrombin clotting time with normal human plasma. The technique of prothrombin time used in this report is that of Quick's venous plasma dilution method.⁴ Since the technical details are of paramount importance in an investigation of this nature, each step of the experimental procedures will be described somewhat at length.

Removal of the Brain.—From 8 to 10 c.c. of air were injected into the hearts of 18 normal rabbits by ventricular punctures, after which within one minute the animals usually died from air embolism. In an attempt to provide as bloodless a field as possible in the brain area, the animals were suspended by their necks immediately after death for approximately fifteen minutes. The brain was then removed from each animal in the following manner:

A longitudinal scalp incision was made between the occipital and frontal regions, so that the scalp could be separated into the lateral flaps. Using a rongeur, a niche was made in the parietal region of the skull. The brain was exposed by carefully chipping away the cranial bone, the movement being in a forward and lateral direction until the olfactory lobes were brought into view,

*From the Departments of Pediatrics, University of Illinois College of Medicine and the University of Chicago.

Received for publication, September 12, 1941.

and at the same time the meninges were also removed. The same procedure was carried out in a backward direction from the parietal region to the foramen magnum, thereby exposing the brain from the olfactory lobes to the spinal cord. Care was taken not to disturb the brain at any time while the rongeur was in the cranial cavity.

A small, flexible spatula was inserted below the olfactory lobes; by pushing it backward to the cerebellum the encephalon was freed from the base of the skull, except for the attachment at the optic chiasma. By moving the animal's head upward and backward through a 120° arc, the brain was easily severed from the optic chiasma. The animal's head was held in this backward position to allow the brain to fall into a position that would reveal the foramen magnum as well as the cranial nerves. By moving the spatula still farther back, the cranial nerves were cut, followed by a transection of the spinal cord just below the foramen. The final step was to cut the meninges at the tentorium cerebelli so that the brain could be completely removed from the cranium by a final upward movement of the spatula.

XIV	1	0.4	3.0	0.15	2.85	0.60	23.2

Preparation of the Brain Powder.—After stripping the brains of the remaining fragments of the meninges and the discernible blood vessels, they were macerated to a smooth paste in a large mortar. This composite of fresh rabbit brains, weighing altogether 97 Gm., was equally divided into two portions. One portion was spread in a thin film over a glass plate, in accordance with the technique described by Magath,³ and dried at 37.5° C. for sixteen hours. The dried brain paste was then removed from the glass by scraping it off in fine flakes with a small flexible spatula. The second portion was dehydrated with acetone and dried as recommended by Quick.²

The Magath and Quick thromboplastins were again divided into two equivalent portions; one part of each preparation was stored at 5° C. in separate tightly stoppered bottles and the other part was kept at room temperature in well-stoppered containers. From this original composite of fresh rabbit brain four types of thromboplastic material were thus available for investigation,

namely: (1) Quick's brain powder stored at 5° C.; (2) Quick's brain powder kept at room temperature; (3) Magath's brain powder stored at 5° C.; and (4) Magath's brain powder kept at room temperature.

Preparation of the Thromboplastic Reagents.—At fortnightly intervals adequate amounts of the four types of thromboplastic material for each series (Table II) were suspended in 19 parts of freshly prepared 0.85 per cent sodium chloride solution, thus making a 1:20 solution.* To insure a uniform preparation of all the thromboplastic reagents throughout this investigation, the suspensions of dried rabbit brain were always made in 9 by 65 mm. test tubes (Kolmer serum tubes). After thorough mixing, the saline suspensions of thromboplastin were warmed for fifteen minutes at 45° C. and then were again thoroughly mixed and finally allowed to stand for sedimentation of the coarse particles. The milky supernatant liquid from each of the four types of brain powder was then transferred to stoppered vials. For one-half of the experiments it was necessary to use several Kolmer serum tubes in order to make enough of one sample of a single thromboplastic reagent for a given series. After the sedimentation of the coarse particles the supernatant liquids from one type of rabbit brain powder were pooled together in the same vial.

Preparation of the Chemical Reagents.—The chemical reagents required in the performance of the prothrombin clotting time determinations in the present investigation were prepared according to the following specifications:

(1) M/40 calcium chloride solution: 0.368 Gm. of $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$ (Baker's special grade) dissolved in 100 c.c. of distilled water.

(2) Physiologic saline: 0.85 Gm. of Merek's reagent NaCl in 100 c.c. of distilled water.

(3) 1.34 per cent sodium oxalate solution: 1.34 Gm. of $\text{Na}_2\text{C}_2\text{O}_4$ (Baker's analyzed grade) in 100 c.c. of distilled water.

Collection of Plasma.—For each series of experiments sufficient blood was drawn from patients with hypertension. If great difficulty was encountered in introducing the needle into the vein, the sample of blood was rejected. A freshly sterilized clean needle and syringe were used for each new venipuncture attempted at a different site. The blood was transferred without delay from the syringe into a tube containing 1.34 per cent sodium oxalate in such proportions as to furnish 1 part of anticoagulant to 9 parts of blood. After thorough mixing of the contents, the tube was centrifuged for fifteen minutes at 2,000 r.p.m. for complete separation of the plasma. Except for the 2 c.c. that was to be immediately used for the analysis, the stock supply of plasma was kept at 5° C. to prevent any possible diminution of its prothrombin activity, as well as any possible deterioration of the plasma itself. As more plasma was needed for the series of tests, 2 c.c. portions were removed from the stock supply.

Assay of the Thromboplastic Material.—The tests performed to assay the thromboplastic solutions thus prepared were carried out at 37.5° C. \pm 1° C. One-fortieth molar calcium chloride solution was kept in a constant temperature water bath throughout the period of examination.

*Experience with various dilutions of rabbit brain powder with normal saline has shown a proportion of 1:20 (Kelley and Bray²) to give the same prothrombin clotting time as that of 1:18 dilution (Quick).

Abbreviations: Q and M indicate Quick's and Magath's thromboplastins. 5, r, and c, immediately following Q and M designate the brain powder kept at 5° C., at room temperature.

In a duplicate setup 0.1 c.c. of plasma was introduced into each serum tube (9 by 65 mm.) containing 0.1 c.c. of physiologic saline, followed by 0.1 c.c. of the thromboplastin to be tested.

After permitting the thromboplastin-plasma mixture to stand at room temperature for fifteen minutes, the tubes were warmed in the 37.5° C. water bath for one minute before the actual test was performed for each tube so prepared. The final step was the addition of 0.1 c.c. of calcium chloride solution, and at the same instant the stop watch was started. The tube was kept in the bath for the first five seconds* and was then held up against a source of light to insure good visibility of its contents. The tube was slowly inverted (about once in two

*Preliminary tests have shown that the prothrombin time values obtained by this technique were identical with those obtained by keeping the tube fixed in another large tube containing water at 37.5° C. and slowly inverted.

and the control. The figures enclosed in the parentheses represent the ages in number of days of the brain powders and of saline suspensions, respectively; F designates a fresh preparation. The sign > means greater than.

seconds) until the final reaction (clot formation) took place, the watch being simultaneously stopped. The results presented in Table II are averages of duplicate values which checked with each other within one second.

Plan of Experiment.—The prothrombin times obtained with fresh preparations of Magath's and Quick's thromboplastins with normal adult human plasma were noted first. The brain powders and the saline solutions were then stored in stoppered vials. All thromboplastin suspensions and part of each type of brain powder were kept at 5° C., the other part being stored at room temperature.

Two weeks later the activities of the original extracts, as well as those freshly prepared from another portion of the original composite of brain powder (by this time two weeks old), were tested on aliquots of one sample of normal plasma. Using this same sample of plasma, freshly made thromboplastin suspensions

from new Magath and Quick brain powders were tested for use as control values. This same plan of investigation was repeated at fortnightly intervals over a period of one hundred and eighty-two days (twenty-six weeks with thirteen bi-weekly testings).

For each experiment all the thromboplastic extracts on hand from the original composite of brain powder were tested and compared with a new solution of thromboplastin made from freshly prepared rabbit brain powder.

COMMENT

The experimental plan employed in the present investigation thus permitted the comparison of the stability of thromboplastic suspensions of various ages (multiples of fourteen days), prepared according to Quick's and Magath's techniques, at biweekly intervals and all from one progressively aging source of rabbit brain powder. This procedure also enabled us to ascertain the duration of the activities retained by Quick's and Magath's thromboplastin suspensions stored at 5° C., and to estimate the stability of suspensions freshly made from brain powders kept at this low temperature as compared with those stored at room temperature.

From the data presented in Table II, the two types of preparation thus tested exhibit decided variation in thromboplastic potency. It is apparent that the rabbit brain powder as prepared by Quick's technique of acetone dehydration is not only more potent in a fresh state than it is when prepared by the Magath incubator-desiccation method, but the saline suspensions made from the Quick powder retain their activity for a much longer period than those made from the Magath preparation. The slight decrease in thromboplastic activity of Quick's brain powder, as evidenced by the negligible prolongation of the prothrombin clotting time, is of no practical importance. It is, however, also evident that Magath's brain powder retains its thromboplastic potency in the same corresponding degree as Quick's preparation, since the prothrombin time obtained by a suspension made from aged powder is practically identical with that obtained by a similar solution prepared from fresh powder. In either instance, in order to safeguard retention of its potency, rabbit brain powder must be stored at icebox temperature in a well-stoppered vessel, since at room temperature changes detrimental to its activity invariably occur.

SUMMARY

Experimental data obtained in 14 series of observations made at biweekly intervals are presented, showing the relative potency and stability of thromboplastins made from both fresh and aging rabbit brain powders prepared according to the techniques of Quick and of Magath.

The results of our experiments demonstrate clearly the greater thromboplastic activity of rabbit brain powder prepared by the acetone-dehydration method of Quick than that of the incubator-dried preparation of Magath. Providing the preparation is stored at 5° C. in a tightly stoppered bottle, this superior potency of Quick's brain powder is retained for a period of at least six months. Likewise, if kept at 5° C., the suspension of rabbit brain powder, whether freshly made or as old as six months, is still capable of yielding pro-

thrombin clotting times practically identical with those obtained by it in its fresh state. The stability of both the dried rabbit brain powder, and its thromboplastic suspensions, which has been demonstrated in the present study, should dispel any doubt in regard to this particular feature and thereby encourage performance of prothrombin tests.

A NEW STABILIZING AGENT FOR NESSLERIZED SOLUTIONS*

ITS APPLICATION TO THE DETERMINATION OF UREA NITROGEN IN BIOLOGICAL FLUIDS

JAMES HUGHES,† NEW YORK, N. Y., AND ABRAHAM SAIFER,‡
JAMAICA, N. Y.

IN THE visual comparison of nesslerized solutions, the eye of the observer is estimating extinction in a region of the spectrum to which the eye is least sensitive (absorption in the violet). For this reason, various substances such as gum arabic and gum ghatti can be added to stabilize the nesslerized solution without altering appreciably the precision of the visual comparison. The same substances, however, affect the photoelectric transmission value markedly. This is presumably the reason why some investigators in applying photoelectric techniques to the nesslerization of ammonia formed from blood urea have eliminated the gum stabilizing agent, but in doing this they have eliminated an important advantage enjoyed in the visual comparison, namely, stability of the transmission value of the nesslerized solution. Thus, Hoffman,⁴ in eliminating gum ghatti, found it necessary to read his samples two minutes after color development and even then could read to only 40 mg. per 100 c.c. (0.016 mg. of urea nitrogen in 10 ml. of solution) of urea nitrogen in blood presumably because of rapid clouding of the sample. In addition, the transmission value of his blank is rather large, i.e., about 71 per cent. Nevertheless, the method is one of the most recent and successful in applying the photoelectric colorimeter to a direct nesslerization procedure for blood urea. In an effort to get back to the advantages of the visual comparison of nesslerized solutions and combine them with

Received for publication, August 10, 1941.

the advantages of the photoelectric colorimeter, we have sought a more efficient stabilizing agent. This paper sets forth what we believe to be our successful findings.

APPARATUS AND REAGENTS

Photoelectric Colorimeter. An instrument similar in design to the Evelyn colorimeter¹ was constructed with a sleeve of variable aperture to take a standard (16 by 150 mm.) pyrex tube rather than the large 25 ml. capacity tube used by Evelyn. However, any photoelectric colorimeter now on the market may be used instead of the instrument described.

Colorimeter Tubes. Tubes are selected from a large batch of pyrex (16 by 150 mm.) tubes and have graduation marks at 5 and 10 ml. They are chosen so as not to differ in transmission by more than 0.2 per cent.

Filter. The proper filter for the yellow nesslerized solution was selected from spectrophotometric data obtained with a Coleman-Bell double monochromator spectrophotometer. Using Corning glass filters, it can be composed by using 2 mm. of glass No. 585 with 3 mm. of glass No. 428. This combination gives a transmission band whose midpoint falls at about 440 m μ .

Water. Triple distilled, ammonia-free water was used for all reagents, standard solutions and dilutions.

Liquoid (Sodium polyanetholsulfonate). Hoffmann-La Roche product, 2 per cent solution in water.

*Urease.*⁶ Treat 10 Gm. of permutit in a liter flask with 100 ml. of 2 per cent acetic acid. Decant off the acid, and wash the remaining permutit three times with distilled water. Add 150 ml. of 0.001 N sulfuric acid and 50 Gm. of jack bean meal and shake for fifteen minutes. Add 200 ml. of glycerol and shake in a shaking machine for one and a half hours. Allow mixture to settle for about one-half hour in the icebox. Then remove supernatant fluid and centrifuge it at 1,500 r.p.m. Transfer the supernatant fluid from the centrifuge tubes to glass stoppered bottles and place them in the icebox. This concentrated extract of urease will keep indefinitely.

Blood Filtrate Reagents. Tungstic Acid: This is a slightly more concentrated form of the Van Slyke and Hawkins⁹ modification of the original Folin-Wu reagents and is made from two solutions: Solution A—Dissolve 111 Gm. of sodium tungstate ($\text{Na}_2\text{WO}_4 \cdot 2\text{H}_2\text{O}$) in water and dilute to one liter. Solution B—Add 6 ml. of concentrated reagent grade sulfuric acid to 1,500 ml. of water and dilute the two liters.

For use, mix one volume of solution A with eight volumes of solution B. For blood filtrate, mix nine volumes of this mixture with one volume of blood.

Somogyi⁷ reagents for zinc filtrate of blood: Solution A—10 per cent zinc sulfate: 100 Gm. $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$ dissolved in one liter of solution. Solution B—0.5N sodium hydroxide. Ten milliliters of solution A should require between 10.8 and 11.2 ml. of solution B to produce a permanent phenolphthalein end point. To prepare 1:10 blood filtrate, take one volume of blood with seven volumes of water. Add one volume of solution A, mix, and then add one volume of solution B. Mix again and filter.

Nessler's Reagent. Sixty-eight grams of the dry Nessler salt (obtained from the Technicon Co., New York City) is dissolved in one liter of 5 per cent sodium hydroxide. Allow to stand several days in a pyrex flask in a dark closet before using. Use the supernatant fluid without disturbing the precipitate.

Since the intensity of color development varies with alkalinity of reagent, an optimum alkali concentration was selected at 5 per cent with the help of the data presented graphically in Fig. 1.

Fig. 1.—Alkali concentration of Nessler's reagent as per cent of sodium hydroxide solution (0.5 ml. Nessler's reagent in 10 ml. dilution).

Standards. Into volumetric flasks weigh out 3.821 Gm. and 2.145 Gm., respectively, of ammonium chloride and urea, dissolve in water, and dilute each to one liter. These were the stock standard solutions of which 1 ml. was equivalent to 1 mg. of nitrogen. (This value for the urea nitrogen stock standard was independently checked by a digestion, distillation, and titration procedure.) Appropriate quantities of 1:10 and 1:100 dilutions of these stock standards were pipetted out for the standards used in making the standard curves. The ammonium chloride and urea were recrystallized from reagent grade chemicals and dried at 110° C.

Stabilizing Agent. Since in nesslerized solutions clouding appears to be a process of gradual agglutination, the possibility of preventing it by means of blood anticoagulating agents was investigated. Liquoid (sodium polyanethol-sulfonate) proved to be particularly effective. It gives very low blanks, is obtainable in pure form, and requires only one drop of a 2 per cent solution to stabilize a 10 ml. volume of nesslerized solution. An idea of liquoid's ability to prevent

cracking of a nesslerized sample can be gained from the fact that 0.25 mg. of ammonia nitrogen in 10 ml. of nesslerized solution could be stabilized for a maximum of sixty minutes with one drop of 2 per cent liquoid, whereas the same solution without liquoid cracked within thirty minutes. In addition, the transmission value stabilized with liquoid falls much more slowly than with the more frequently used stabilizing agents, such as gum ghatti, gum arabic, gum senegal,² etc.

PREPARATION OF STANDARD CURVES

Our particular field of application of nesslerization is the direct determination of urea nitrogen in blood filtrate. Therefore, in the preparation of the standard curves an effort was made to have the standard solution conform to the actual condition of a blood filtrate. To this end, the average concentration of the tungstic acid remaining in a blood filtrate was determined³ and found to be about one-fourth that used in the precipitation of the blood proteins. This quantity, therefore, was added to each standard solution. In Somogyi filtrates the concentration of the remaining zinc ion is small and can be approximated by adding 1 ml. of filtrate obtained from the mixing of the Somogyi reagents with distilled water used in place of blood.

Standard Curves for Zinc Filtrates.—Into tubes graduated at 10 ml., quantities of standard urea solution were pipetted so that the nitrogen concentrations (after treatment with urease) would be those contained in 0.1 ml. samples of blood, ranging from 5 to 70 mg. per 100 c.c. of urea nitrogen. One drop of urease extract was added to each tube and after fifteen minutes' standing at room temperature, the tube contents were treated with the Somogyi filtrate reagents, mixed, and filtered through Whatman No. 2 (9 cm.) filter paper. One milliliter of this filtrate was placed in a colorimeter tube and one drop of liquoid was added. Five milliliters of water and 0.5 ml. of Nessler's solution were next added, and the tube contents were diluted to 10 ml. and mixed. Each standard was run in triplicate and read in the colorimeter at various time intervals against a distilled water blank.

To gain an idea of the thoroughness of conversion of the urea to ammonia by this technique, quantities of ammonium chloride standards were pipetted into a second series of colorimeter tubes so that the ammonia nitrogen would be that contained in 1 ml. samples of blood filtrate (equivalent to 0.1 ml. blood) resulting from bloods ranging from 5 to 70 mg. per cent in urea nitrogen. One milliliter of zinc hydroxide filtrate obtained from the mixing of the Somogyi reagents (water replacing blood) was added to each tube followed by the addition of one drop of liquoid solution, 5 ml. of water and 0.5 ml. of Nessler's solution. The tube contents were diluted to 10 ml., mixed, and read in the photoelectric colorimeter at various time intervals. Each standard was run in triplicate. The transmission values of *both* these sets of standards fall on the same curve. The thirty-minute values are plotted in Fig. 2, where the coincidence of both sets of values is illustrated.

Another set of values was obtained for the same series of ammonium chloride standards used above, with 1 ml. of a 1:4 dilution of tungstic acid

filtrate reagent (water replacing blood) substituted for the zinc hydroxide filtrate used. The thirty-minute transmission values for these are also plotted in Fig. 2, and it is seen that they fall on a different curve. No urea nitrogen values are given on actual tungstic acid filtrates because the products of the enzymatic digestion of urea with the urease extract do not give a clear filtrate in the absence of blood or other protein-containing material. However, by analogy from the coincidence of the two standard curves based on standards containing zinc hydroxide filtrate and good recovery values of urea nitrogen using the tungstic acid curve, it is reasonable to assume that the curve based on ammonium chloride standards and tungstic acid will give transmission values very close to those that would be obtained from equivalent quantities of urea treated with urease.

Fig. 2.—Transmission curves for colorimetric urea method for tungstic acid and zinc filtrates.

PROCEDURE FOR UNKNOWN AND RECOVERIES

In the routine estimation of blood urea nitrogen 1 ml. of blood is treated in a test tube with 1 drop of urease extract and left to stand at room temperature for fifteen minutes. Nine milliliters of tungstic acid reagent (if zinc filtrate is preferred, zinc filtrate reagents may of course be used) are then added, and the mixture is well shaken. After another five minutes' standing, filter through a Whatman No. 2 (9 cm.) filter paper. One milliliter of the filtrate is placed in a colorimeter tube, followed by 1 drop of liquoid, 5 ml. of water, and 0.5 ml. of Nessler's reagent. The tube contents are then diluted to 10 ml.,

†Cerebrospinal fluid.

mixed, and read in the colorimeter at the end of thirty minutes, or at whatever time interval the standard curve is made. Other biological fluids are treated in the same way. However, one to ten dilutions are first made on urine specimens to bring their urea nitrogen content down somewhere within the range of the standard curve. The diluted sample is then treated exactly as for blood. Occasionally samples will be obtained with urea values so high that it will be desirable to repeat the determination on a smaller sample. If, however, a smaller sample is not available, an aliquot (α) of the 10 ml. volume in the colorimeter tube is taken and placed in another colorimeter tube, and $0.5 (1 - \frac{\alpha}{10})$ ml. of Nessler's reagent is added. The tube contents are then diluted to 10 ml., mixed, and read in the colorimeter. If the extra Nessler's reagent is omitted, the trans-

mission value of the diluted sample will be too high. By this means the range of the method can be extended to ten times the range of the standard curve, i.e., 700 mg. per 100 c.c.

In Table I are given the urea nitrogen values obtained from tungstic acid filtrates of various kinds of biological fluids and urea nitrogen recoveries on these same fluids. The base values of the urea nitrogen content of these various samples are compared with those obtained by distillation and titration of the ammonia resulting from the urease treatment of the same filtrates. Values obtained by both methods are seen to be in good agreement. The recoveries, together with these compared values, are good enough to justify the use of the tungstic acid-ammonium chloride standard curve.

DISCUSSION

The extra buffer solution that is customarily employed in urea determinations to provide the optimum pH for action of the enzyme, urease, is omitted, because with the concentrated stable extract of urease used, it adds nothing to the completeness of conversion of the urea present.

Tungstic acid filtrates instead of zinc filtrates are prepared in this laboratory where daily filtrates sometimes number in excess of 100, because they require only a single reagent, whereas zinc filtrates require at least two, and with the original Somogyi technique, three, if the distilled water for the proper volume dilution is considered. In using tungstic acid filtrate we did not encounter the high blanks of which Hoffman⁴ complained.

Since the transmission value of a nesslerized solution falls slowly, the standard curve should be made for a definite time interval, and the unknowns should be read at this interval.

In the practice of photoelectric colorimetry some writers⁸ criticize the use of standard curves because they feel that the conditions under which the curve is prepared at one time, and those under which an unknown is read at another, are never exactly duplicated, and, therefore, choose to compare their unknown with a freshly prepared standard, and to get their result from the familiar inverse proportion based on the Bouger-Lambert-Beer law. This is sound practice when the law holds. In defense of our using a standard curve, we wish to point out that in many cases the Bouger-Lambert-Beer law holds only in a limited range of lower concentrations and deviates considerably at higher concentrations. Therefore, calculations based upon it often contain more error than would be introduced by use of a standard curve whose duplicability had been checked over a long period of time. The standard curves illustrated in this paper have been used and checked over a period of two years and furnish, we believe, an example of a set of conditions that can be sufficiently duplicated to validate their use.

Although the standard tungstic acid curve presented is especially prepared for blood filtrates, and an amount of tungstic acid is placed in the standards that approximates that in blood filtrates, the curve is usable for estimating the urea in tungstic acid filtrates on biological materials other than blood. This is apparent from the results given in Table I, which were obtained by use of this curve.

SUMMARY

A new stabilizing agent, liquid, is offered for nesslerized solutions that gives very low blanks and stable transmission values. The technique is applied to urea determinations on the filtrates of biological fluids that have been treated with urease.

MEDICAL ILLUSTRATION

FLUOROGRAPHY*

LLOYD E. VARDEN, A.R.P.S., BINGHAMTON, N. Y.

DEFINITION

FLUOROGRAPHY is the process of recording, by use of an optical system and light-sensitive film, the image formed upon a fluorescent screen (1) by a differentially absorbed beam of radiant energy, usually roentgen rays; or (2) by a stream of directed electrically charged particles. The process, then, includes the photographic recording of fluoroscopic images found in medical or industrial radiology, the photography of television images, the photography of cathode-ray oscillograph patterns, and similar images. Fluorography definitely does not encompass all types of photographic recording in which fluorescence is utilized. For example, contact radiography in which a light-sensitive film is most frequently, but not necessarily, sandwiched between two fluorescent screens is not considered to be fluorography; nor are such methods as described by Dershem,¹ wherein a directed beam of fluorescent x-radiation is used to record the distribution of certain elements in a thinly sectioned specimen, by selecting as the fluorescing substance an element whose characteristic K-radiation corresponds closely to the K absorption limit of the element to be detected; nor, in spite of the similarity of name, is the so-called fluoroscopic process,² invented by W. S. Marx, Jr., in 1938 in any way related to fluorography. This latter process is a special procedure for producing so-called "high-light" half-tone screen negatives for use in photomechanical reproduction.

The process now called fluorography is, however, known also as indirect radiography, fluoroscopic screen photography, fluorophotography, miniature radiography, fluororadiography, microradiography, and roentgen photography, and at one time was called photofluoroscopy. It is interesting to note that the term which has been adopted through usage is the most simple. At a time when there was some question as to the etymologic correctness of the term fluorography, I approached the heads of the English departments in three leading United States universities with the question independently, and in each case, after learning the nature of the process and reviewing the names which had at one time or another been used to describe it, these authorities selected fluorography as the most logical term to adopt.

HISTORY

Roentgen discovered x-rays in 1895. In the following year several means were devised for photographing the fluoroscopic image excited by these rays.

*From the Agfa Ansco Product Information Department, Binghamton.
Read at the Meeting of the Biological Photographic Association, September, 1941.

MacKay³ described one method in March, 1896; Bleyer⁴ constructed his photo-fluoroscope in April, 1896; Battelli and Garbasso⁵ also described a method in January of the same year. In 1897 Porcher⁶ published an article entitled, *Photographie de l'image fluoroscopique*. In 1897 McIntyre⁷ published an article describing indirect radiographic motion pictures which he accomplished during a series of experiments in 1896 by photographing the shadow image formed on a potassium platino-cyanide fluorescent screen. At this period there was a sharp turning point with respect to the manner of making radiographic records. Initially, the photography of the shadow image formed on the fluorescent screen was the preferred method, but Porcher⁶ and others were of the opinion that the results obtained in indirect radiography were unsatisfactory, and hence the direct method gained favor. A few years later Köhler⁸ anticipated the promising future of fluorescent image photography; in 1909 Biesalski and Köhler⁹ outlined a practical method for conducting the work in which were utilized a calcium tungstate screen (blue fluorescence) an F/2 lens, and a mirror permitting the camera to be placed outside the direct beam of roentgen rays. This revival of the indirect procedure by Köhler gained momentum as time went on, and within a few years nearly all the problems involved in the process had been recognized.

Caldwell¹⁰ in 1911 published an important paper on indirect radiographic still photography and cinematography in which he set down practically all the essential principles concerning the application of fluorography. He employed a 4 by 5 inch camera and a F/4.5 Cooke lens in conjunction with a "Gehler Folie" for still work. The screen that Caldwell used had a short phosphorescent afterglow which, as pointed out by Hirsch,¹¹ anticipated the most suitable screen available today for fluorography—the "fluorazure" screen, more properly known as the photo-roentgen screen, which has an afterglow also, but as used in practice it does not persist long enough to interfere with the clarity of the recorded image.

Loman and Camandon¹² were the first to utilize an extremely wide aperture lens in fluorography. In 1913 they employed a lens of F/1.55 relative aperture for motion pictures of the fluoroscopic image.

It is doubtful if much of this early photography of the fluoroscopic image was successful, especially the motion picture photography.* The problems involved were well understood, but the limitations were too severe to permit satisfactory results. It was not until lenses of wide aperture were generally available, until photographic emulsions were made faster, and until more efficient roentgen-ray tubes and fluorescent screens were devised that fluorography produced results worthy of evaluation.

APPLICATIONS

Although categorically fluorography includes the photographing of fluorescent screen images of any type, the widest field of application is found in medical radiology. Nearly the entire development of the process has been con-

*This view is based somewhat upon the private communication from S. L. Warren, Rochester, N. Y., reported in the *Science of Radiology*, page 204, edited by Otto Glasser (1933), in which it is claimed that after five years' labor it had been found impossible to achieve a satisfactorily sharp image in cinefluorography with the use of lenses of very wide aperture. This statement had reference to the publication of Luboschew,²² who had reported good results in 1929 by means of a lens of F/0.65 relative aperture.

tributed by medical researchers and roentgen-ray technicians, their reports being published in medical and allied journals. In medical radiology there are two distinct applications of fluorography, single and serial exposures. Both applications are important, and the same technical problems in attaining suitable results are involved. In serial fluorography the successive exposures frequently can be made sufficiently rapid to permit the taking and subsequent projecting of roentgen-ray motion pictures.* This branch is called cinefluorography.

Single exposures of the fluorescent image are made for purposes of record or diagnosis, or both. For group studies of large populations, as in thoracic surveys, fluorography represents a distinct advantage over contact radiography, especially from an economy standpoint. This branch is known as collective fluorography and the individual records are called fluorograms.

In Germany the application of fluorography in medical diagnosis is regarded as limited to the determination of lung shadows, disease centers of sizeable area, and the frequent detection of active tuberculosis. It is not considered suitable for showing satisfactory bone structure, nor early infiltrations in pulmonary disease, such as early tuberculosis and early silicosis.¹³ However, Hirsch¹¹ in this country, with reservation similar to that of the Germans but with a somewhat more optimistic outlook, states that fluorography is: 1. Applicable to the study of the skeleton in delineating *gross* bone changes and deformities. 2. Useful in gastrointestinal surveys, particularly in the study of the colon and in motility tests. 3. Suitable for showing clearly the position and shape of the heart and, upon applying proper correction factors, the heart shadow diameters can be determined according to the usual method. 4. Valuable in the study of the lungs, particularly for tuberculous changes, the records being sufficiently clear to permit the differentiation of the normal from the abnormal lung.

Manoel de Abreu,¹⁴ who in 1936 inaugurated the first installation of fluorographic apparatus for the purpose of carrying out a mass examination in Rio de Janeiro, also is of the opinion that fluorograms yield useful diagnostic evidence. His enthusiasm for the process is largely responsible for the installation of numerous fluorographic outfits throughout Brazil and other South American countries. Abreu's influence was not limited to South America, for he acquainted D. O. N. Lindberg of Decatur, Ill., with the success of his work, and Lindberg brought the method to the United States in 1937.

Cinefluorography has been found by Stewart and Ghiselin¹⁵ to be safer and more effective than other radiographic procedures in the study of abnormal diaphragm and mediastinal movements in the understanding of pulmonary disease. In an earlier paper these same workers¹⁶ reported that cinefluorography had several advantages over direct fluoroscopic examination in the study of many moving organs, such as the heart. They claimed, in addition to other factors, that the motion picture was even more defined than was observation with the best possible fluoroscopic screen. In a similar vein Böhme^{16a} expressed the merits of cinefluorography in studies of the heart. He used the process to

*So-called x-ray or roentgen-ray motion pictures are not entirely "real." The motion picture record is actually only a repetition of a single cycle which gives the effect of a continuous action. However, single cycles of an organ do not constitute a full study of the organ, since some cycles may be normal whereas others may be pathologic.

demonstrate his discovery regarding the important function of the auriculo-ventricular diaphragm in the propulsion of blood. He was able to make as high as 150 exposures per second for short intervals of time, three to four seconds.

Outside the medical fields fluorography has had a scattered but significant application. With the coming of an increased use of fluoroscopic roentgen-ray examinations in industry for quality control, it is natural to assume that there would be a corresponding increase in the number of photographic records desired. Moreover, the growth in the uses for cathode-ray tubes has occasioned an increase of interest in retaining records of traces in certain experimental and even in routine studies.¹⁷ Dudley¹⁸ has published an article on the photographic recording of television images. Undoubtedly interest in this branch of fluorography will gain in application as television becomes more practical.

There are many optical and photographic problems which pertain to fluorography, and in view of the likelihood that the process will find wider application in medicine, industry, and science, it is deserving of more extensive study.

FACTORS IN OBTAINING OPTIMUM RESULTS

The aim in fluorography is specifically to reproduce as accurately as possible the fluorescent screen image with a maximum of sharpness and with adequate contrast to permit evaluation of details. In medical applications an additional aim, of course, is to replace radiosopic examination by a less dangerous method and, in addition, to offer better documentation.¹⁹⁻²¹ Whether or not the aims are satisfied is determined by the conditions of operation and the acumen with which the situation as presented by the limitations of equipment is met. First results are often disappointing, simply from a lack of appreciation for the problems involved. The alacrity with which an individual technique is evolved will be influenced vastly by the extent of one's knowledge of the overall problem.

There are several factors that govern the quality of the result.^{13, 19, 22-24}

1. The efficacy of the radiant energy or electron stream to excite fluorescence. In the case of medical radiology, the energy of the incident roentgen-ray beam is limited by the capacity of the tube and by the tolerance of the patient's skin.
2. The light-producing power of the fluorescent screen, which varies qualitatively and quantitatively according to:
 - (a) The chemical composition of the screen.
 - (b) The color energy distribution of the fluorescent radiation.
3. Sharpness factors which are dependent upon additional screen characteristics, namely,
 - (a) Graininess of screen structure, whether coarse or fine.
 - (b) Time lag of screen.
4. Characteristics of the camera lens which include:
 - (a) Light-gathering power; that is, the lens speed.
 - (b) Sharpness of the lens at wide apertures.
5. Sensitivity of the film to light energy emitted by the screen.

It is not convenient to discuss these various factors in the order given. Because the process of fluorography involves the use of an optical system, it is best

to outline first the limitations which this imposes. Moreover, it is the use of an optical system that chiefly distinguishes fluorography from normal roentgenographic procedures in which the recording film and screens are in actual contact. However, it is the matching of the quality of the large roentgenogram, made in the normal manner, by the indirectly made reduced image that more or less establishes the quality criterion for fluorography.

d equals aperture of lens
 f equals focal distance
 a equals screen-lens distance

$$\frac{\pi d^2}{4} : 2\pi a^2 \quad \text{or} \quad \frac{d^2}{8a^2}$$

Fig. 1.

In contact radiography* the entire radiation within an angle of 180 degrees, and even more when screens are used on both sides of the film, is utilized in exposing the film. With a lens system the amount of radiation received by the film is limited at the outset by the acceptance angle of the objective. This requires, of course, a brighter screen image in fluorography than is necessary in normal roentgenography, but since this in turn demands an increase in the total energy output of the roentgen-ray tube, it is desirable to employ the fastest possible photographic objectives. Lenses of relative aperture in the range of from $F/0.53$ to $F/0.625$ have been used in cinefluorography,²⁵⁻²⁷ but such lenses are not readily available nor could they be made of sufficient focal length to cover a large field. The Zeiss R-Biotar objective is available with a maximum F value of 0.85, 4.5, or 5.5 cm. focal length, but the overall sharpness cannot be regarded as entirely satisfactory. Much more satisfactory results are obtainable with the Zeiss Biotar $F/1.4$, 7 cm. focal length, or with the standard Contax, Leica, or Ektar $F/1.5$ to $F/2.0$ objectives. Furthermore, it is preferable to have even these objectives surface-treated to minimize internal light reflections, otherwise the resultant loss in image contrast would have to be gained through an increase in the brilliance of the screen image or by the use of a film of exceptionally steep exposure-density gradient.

A mathematical approach to the determination of the conditions for optimum results has been made by Bouwers,¹⁹ which is an expansion of a former work concerning the so-called law of uniformity.²⁸ This law is concerned with the factors which are causes for unsharpness in the normal roentgenogram of objects in motion and specifically states that optimum conditions are reached when the factors are equal; thus,

$$U_m = U_k = U_s \quad (1)$$

*It should be noted that television and other cathode-ray tube tracings can be recorded by contact methods but less conveniently than by means of a camera.

where U_m is the unsharpness resulting from movement, U_g is the geometrical unsharpness, and U_s the unsharpness caused by screen factors. Mean values of U_g and U_m are assumed since these factors are not constant for the whole image. The law of uniformity is based upon the fact that the product of U_m , U_s , and U_g is a measure of the amount of light reaching the film and, for a given value of the product, a given image density is achieved. However, the sum of three numbers with constant product is smallest when the numbers are equal; therefore, we get equation 1, since the total unsharpness is the sum of the three unsharpness factors.

Although the law of uniformity originally applied to normal radiography, it is equally applicable to fluorography, provided, as in the case of normal radiography, that a rotating anode tube is used. For example, if we assume that proper radiographic conditions for optimum results are established, we can eliminate one contact fluorescent screen and photograph the image on the remaining screen with a lens and camera. With the fastest practical lenses the light per square centimeter incident upon the film in the camera is only one-tenth that per square centimeter incident upon the film when in contact with two fluorescent screens. Accordingly, if a film of the same sensitivity as the normal roentgen-ray film were used, and the energy output from the tube remained constant, then an exposure increase of twenty times would be required for the camera exposure. However, such a vast increase in *time* of exposure would increase U_m to an intolerable extent and at the same time the life of the roentgen-ray tube would become endangered, not to mention the danger involved by giving the patient such a large roentgen-ray dose.

Fortunately, the law of uniformity can be applied to show what changes are required to establish exposure conditions for optimum results. Since

$$U_m = U_g = U_s$$

and since in the case at hand

$$U_m \times U_g \times U_s = 20X$$

the new conditions will be best if each unsharpness factor is multiplied by

$$\sqrt[3]{20} = 2.7$$

in order to increase its product by a factor of twenty. These conditions could be met by the use of a tube of wider focus, by means of a somewhat coarser grained screen of greater layer thickness, and by increasing the time of exposure now by only 2.7 times. The unsharpness in the final reduced image is then only 2.7 times greater than in the direct double screen image. From this it is apparent that the loss of sharpness in the small image is determined by the ratio of the amount of light per square centimeter in the small image, I' , to the amount of light, I , that would be available per square centimeter of film surface in the direct method. Therefore, if we denote the increase of unsharpness by the factor k , its magnitude is determined by

$$k = \sqrt[3]{\frac{I}{I'}} \quad (2)$$

As previously mentioned, this deduction is based upon equal film sensitivities which at present, at least, can be assumed to be approximately true. There are

also additional factors that are ignored, otherwise the treatment becomes unduly complicated. For example, no regard is given the fact that fluorograms are projected and accordingly can be of a lower density level than normal roentgenographs.

The calculation of the ratio of $I' : I$ can now be considered. In Fig. 1 the geometric relation between the screen, camera lens, and reduced image plane are shown. If d is the aperture of the lens, f its focal distance, and a the screen lens distance, then the relation of the light passing through the lens to the total light emitted by the screen is

$$\frac{\pi d^2}{4} : 2\pi a^2 = \frac{d^2}{8a^2}$$

If the reduction is n times, then the surface area over which the light passing through the lens is distributed will be $\frac{1}{n^2}$ that of the screen; consequently, the brightness of the reduced image becomes $\frac{n^2 d^2}{8a^2}$ times that in a film in contact with one screen, or $\frac{n^2 d^2}{16a^2}$ times that in a film between two screens. But,

$$n \cong \frac{a}{f}, \text{ so } \frac{I}{I'} = 16 \left(\frac{f}{d}\right)^2 \quad (3)$$

Now, by equation 2 we obtain for the increase in unsharpness the factor,

$$k = \sqrt[3]{16 \left(\frac{f}{d}\right)^2} \quad (4)$$

It so happens that it is an advantage to use a higher voltage for fluorography than is favorable for direct roentgenography. By so doing an increase in sharpness follows, since the tube output is increased and results in a smaller product for $U_s \times U_m \times U_g$ for a given image density. This increase in tube voltage also decreases the factor I/I' . Now if in addition to this, the focus screen distance is reduced, a gain in light intensity can be effected. As a matter of fact, the sharpness can be doubled in the small image by increasing the tube voltage by 30 per cent and by reducing the focus-screen relation to one-half.

A new unsharpness factor can be established if these compromises are made, since equation 4 becomes

$$k' = \sqrt[3]{4 \left(\frac{f}{d}\right)^2} \quad (4a)$$

when the tube voltage is increased 30 per cent and the focus-screen distance is halved.

The values of $\frac{f}{d}$, as we have noted, are generally not smaller than about 1.5. Substituting this in formula 4a, the unsharpness factor becomes 2.08. This amount of unsharpness, according to Bouwers, corresponds to the relative sharpness acquired with rotating and stationary anode tubes.

From these calculations, which comply rather closely with practice, it is clear that there is room for improvement in the comparative quality of fluoro-

grams as made in medical roentgenography. However, the present results under the best conditions compare favorably with the quality of direct roentgenograms of an earlier period, and so for many applications can be considered adequate.

Sharpness Factors Dependent Upon Screen Characteristics.—In the foregoing calculations Bouwers²⁸ eliminated the unsharpness resulting possibly from the lens and film by assuming that these would be small in comparison to the unsharpness caused by other factors, even under conditions conducive to ideal reproduction. (The elimination of the lens as a factor becomes more acute in cinefluorography, for here the demand for wider aperture and greater sharpness are both encountered.) He assumed that miniature camera films of the fine grain type would be employed, but actually in modern fluorographic practice special films are coming to the fore. The films have an exceptionally high sensitivity to the fluorescence emitted by available photo-roentgen screens, and in addition are of rather steep inherent contrast. However, the graininess of these films compares favorably with the graininess of modern high speed roentgen films. Nevertheless, in relation to the unsharpness introduced by the grain structure of the screen as well as other factors, the film is well within the permissible limits as far as these concern the ability of the film to register fine detail, viz., resolving power. For example, if we assume the unsharpness in a normal radiographic image to be of the order of 1 mm.,* the magnitude of the unsharpness in a 15 diameter reduction would be about 0.07 mm. The resolving power of the film, then, is required to be less than 10 lines per millimeter, which is far inferior to present emulsion standards even for coarse grain films. This means that the extent factor of unsharpness here rests with the nature of radiographic imagery and the fluorescent screen. The size of the focal spot and other factors determine the sharpness of the image primarily, but the coarser the grain of the screen the less fine detail will be discernible. However, since increased light emission accompanies an increase in grain size of the screen, there must be an optimum condition that can be met. Actually, the emission characteristics of the screen should be a maximum for a given amount of excitation, but this should not be carried to a point that will give an unsharpness greater than that presently accepted in normal radiography. It would be ideal, of course, to have a screen of high emissivity and of very fine grain structure.

The phosphorescent lag of the screens used in modern roentgen-ray practice is generally nil. And certainly there can be no appreciable lag in the screens adapted for cathode-ray tubes in television and in oscillograph manufacture. However, as previously pointed out, with the special blue fluorescing Patterson photo-roentgen screen there is a persistence of image, but this is of no consequence in the methods used in still fluorography. If anything, the afterglow slightly increases the image density without causing deleterious effects. Screens that are employed in cinefluorography can exhibit no persistence of image. For this work the Patterson fluoroscopic, type B, screen is excellent. A special study of the lag effect has been undertaken by Hirsch.^{29, 30} He found that by permitting the camera shutter to remain open five minutes after the short ex-

*It should not be inferred from this discussion that the screen is the chief cause of unsharpness in the normal radiographic image. The screen unsharpness is of the order of 0.15 to 0.17 mm., according to measurements made by the Patterson Screen Co. These data are corroborated by measurements published by H. Mermagen, x-ray technician, September, 1939.

citation period and by using a special screen with pronounced lag, an appreciable gain in image density resulted, but only at a sacrifice of overall contrast.

The Light-Producing Power of the Fluorescent Screen.—The exact chemical composition of commercial fluorescent screens is not available, nor is such information of particular value. It is known that certain compounds, when properly crystallized and dispersed, exhibit fluorescent properties to a greater or lesser extent, and that the color of the light varies according to the particular substance used. Roentgen-ray intensifying screens are dependent upon calcium tungstate for their fluorescence. Today these screens exhibit no lag, although at one time this represented a considerable problem. Minute quantities of certain metals are known to eliminate afterglow; for example, as small an amount as 10^{-6} Gm. of nickel added to a zinc sulfide layer is sufficient. However, regular intensifying screens are not used in fluorography. Instead, zinc sulfide fluoroscopic screens of either blue-green or blue fluorescence are preferred. The color energy distribution of the fluorescence for the various types of screens is given in Table I.

TABLE I

TYPE	SPECTRAL EMISSION
Intensifying screens - - - - - (Calcium tungstate)	3,800 to 5,200 A. (Maximum band at approximately 4,300 A.)
Fluoroscopic screens - - - - - (Patterson photo-roentgen or fluorazure)	3,900-4,900 A.
Fluoroscopic screens - - - - - (Type B)	5,200-6,000 A. (No sharply defined maximum band is exhibited by either type of fluoroscopic screen.)

Sensitivity of Film to Light Energy Emitted by Screen.—Either standard film products or special films can be used in fluorography. It is preferable to use a film of high contrast, and one which is especially sensitive to the radiation emitted by the fluorescent screen. A film of this type, developed by Agfa Ansco, is known as "Fluorapid."

The spectral sensitivity of Fluorapid film is represented in the wedge spectrogram, Fig. 2. It is readily apparent that the major part of the sensitivity of the film is between 4,000 and 5,700 A. This range is suitable for both the photo-roentgen and type B fluorescent screens.

The total sensitivity of Fluorapid film to the light of the photo-roentgen screen is especially high, being equal to, or slightly faster, in the threshold region than in the high-speed roentgen-ray film emulsions. In addition to having a speed equal to the fastest emulsions available today, it also has a relatively steep exposure-density gradient. As shown in Table II, the film can be developed in roentgen-ray type developers to gamma values of over 1.8 which, in comparison to a regular miniature camera type film of similar speed, is exceptionally good.

Other types of films can be used in place of Fluorapid film when the Patterson type B fluoroscopic screen is used. Since the spectral emission of this

screen falls between 5,200 and 6,000 Å., high speed panchromatic emulsions, such as Agfa Ultra-speed, are satisfactory, as well as Fluorapid. For cine-fluorography, a reversible type film, such as Agfa Triple S Pan reversible, is suitable. Films of the Fluorapid type are, however, generally better than other films for both the photo-roentgen and the Patterson B screen and, in addition, have been found excellent for the photography of television images and cathode-tube tracings.*

METHODS, APPARATUS, AND MATERIALS

The actual making of a fluorogram consists simply of photographing the image of the fluorescent screen with a Leica, Contax, or other similar camera, equipped with an F/1.5 or F/2 lens, and loaded with a suitable film. In radio-graphic practice the roentgen-ray tube, the patient, the fluorescent screen, and the camera are placed in direct line with each other and properly spaced. The most simple arrangement, of course, is to place the camera on a firm support and direct it toward the screen. It is advisable, if not absolutely necessary, to place a thick piece of lead glass in front of the camera lens to absorb any of the direct roentgen rays that might fog the film. As previously mentioned, to avoid the effect of the direct roentgen rays Biesalski and Köhler⁹ photographed a mirror

*By using a Contax camera, F/1.5 lens and Agfa Fluorapid film, cathode-ray oscillograph signals as short as 0.0003 second were recorded with good density. The size of the screen image on the film was about $\frac{3}{16}$ inch. Previous to the actual exposure for recording the signal, an image of the dimly illuminated screen was produced on the film with a one second exposure.

image of the screen which permitted the placement of the camera outside the beam of direct radiation. However, this practice has not been followed by modern workers, such as de Abreu¹⁴ and Hirsch,^{11, 20, 30} who utilize a straight line system of almost identical specifications. The apparatus of de Abreu is mounted somewhat more elaborately than that of Hirsch, but the method of Hirsch is far more readily set up by the average clinical photographer. An illustration of his apparatus is shown in Fig. 3, A and B.

Fig. 2.

A 35 mm. type camera* is preferable for fluorography in medical roentgenography for the following reasons: 1. The new type films, such as Agfa Fluorapid, are available only in this size. 2. Lenses of F/1.5 or F/2 relative aperture are standard equipment with several 35 mm. cameras. 3. The fluorograms in survey studies are made in great numbers and rapidly. This means that a camera which can make sequence exposures easily and rapidly is required, as well as a conveniently developed film. 4. The fluorograms are viewed by projection and projectors readily available and convenient to use. 5. The small film sizes are economical.

The lens of the camera should be of the highest quality in order to give an acceptably sharp image over the entire 24 by 36 mm. film area at wide open apertures. Hirsch lists the available lenses of F/1.5 relative aperture, or slightly faster, that can be considered. It would seem advisable to test any lens under consideration by a procedure such as that outlined by Gardner³¹ in the Bureau of Standards Research Paper No. C 428. This publication not only provides a simple and accurate lens testing procedure, but also includes a carefully prepared lens test target.

It is not the purpose of the present discussion to delve into the qualities of various roentgen-ray equipment for fluorographic work. The general assump-

*Rather recently special 4 by 5 inch fluorographic equipment has been introduced for which ordinary high-speed roentgen-ray film has been found quite adequate. Such cameras are now employed by the army for group radiographic examinations, but as yet the 4 by 5 inch size has not won favor over the 35 mm. record for obvious reasons. Nevertheless, when lenses of high speed capable of covering a 4 by 5 inch field are generally available, this size is likely to surpass the 35 mm. method in popularity. For example, from a comparative study made by Plunkett, Weber, and Katz³² it was concluded that 4 by 5 inch images were more suitable because of greater accuracy in reading; slightly better economy, resulting from fewer re-examinations; fewer 14 by 17 inch examinations to effect correct diagnosis; and less strain visually in examining 4 by 5 inch negatives than in the case of 24 by 36 mm. images.

tion is that any equipment of 150 Ma. capacity in conjunction with a roentgen-ray tube of the rotating anode type, capable of operating at 100 kv. loads, is adaptable to the process. For a guide in exposure, Table III has been prepared giving the data recommended by various workers.

PROJECTOR FOR VIEWING FLUOROGRAMS

Fig. 4.

For the processing of the film, standard roentgen-ray developing and fixing solutions are satisfactory. The film can be looped around suitable racks if long lengths are employed, or small 35 mm. film developing tanks can be used for standard 5½ feet, 35 exposure lengths.

The fluorograms are projected when viewed, and for this purpose any number of adequate 2 by 2 inch slide projectors are available. A diagram of the projection arrangement used by Hirsch is shown in Fig. 4.

A convenient magnification of the fluorogram does not yield an image as large as the screen image, but if a 6.8 times enlargement is used, the size will be 15 per cent smaller than half size. For the average chest, this 15 per cent undersize just corrects for the distortion introduced by the use of a 30 inch target-screen distance and accordingly gives a true half-size view.

CONCLUSIONS

The advantages of fluorography in medical roentgenography are, chiefly, simplicity and economy in conducting mass examinations. The economy comes

from the lower cost of small-sized film and subsequent economies in developing and filing. The cost of the film is approximately 2 per cent of that of 14 by 17 inch roentgen-ray film. Perhaps the best discussion on the economy and also on the advantages of fluorography that has been presented is contained in the article by Hirsch,²⁹ to which reference can be made. A vital comparison between fluoroscopic examination and the fluorographic method made by Hirsch is that 350 fluorograms can be read an hour while only 250 fluoroscopic examinations can be made a day by one person. Not only is the process more rapid than direct examination, but it is more dependable, and in addition furnishes a permanent record. Of course, fluorograms cannot compete with large-sized radiographs with respect to image detail and general applicability. However, fluorography certainly has its place in preventive medicine. It is a process with which every clinical photographer should become acquainted.

24. Private communication from W. H. Turner, The Patterson Screen Co. It is stated that the calcium tungstate used in the Patterson intensifying screens and the zinc sulfide glow present would be of the magnitude of small fractions of a second. However,

the Patterson Photo-roentgen or Fluorazure fluoroscopic screen has a definite afterglow. These screens as used in fluorography do not have a sufficiently persistent afterglow to influence the results. The persistence of the afterglow is in relation to the excitation energy received by the screen. A heavy dosage of roentgen rays or daylight would cause an afterglow as long as a half hour. This afterglow can be quenched by exposing the screen to deep red or infrared radiation. (See also Fluorescence and Phosphorescence, E. Hirschlaff, New York, 1939, Chemical Publishing Co.)

DEPARTMENT OF ABSTRACTS AND REVIEWS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

STERNAL MARROW, Changes During the First Week of Life. Correlation With Peripheral Blood Findings, Shapiro, L. M., and Bassen, F. A. Am. J. Med. Sc. 202: 341, 1941.

Peripheral blood studies and sternal puncture examinations were made on 35 normal full-term infants in the first twenty-four hours of life and again one week later.

The peripheral blood findings agreed with those of many other investigators. The authors noted initial high levels of red blood cells, hemoglobin, white blood cells, and reticulocytes. There was a moderate decrease in red blood cells and hemoglobin, a sharp fall in white blood cells and reticulocytes, and a change in the differential from myeloid to lymphocytic predominance at the end of the week.

The most striking finding in the bone marrow was a marked drop in the erythroid elements at the end of the first week of life. This finding, reflected in the peripheral blood by the decreasing reticulocytes, is evidence of curtailed production of new red blood cells. Consequently, the authors offer the idea that the fall in red blood cells and hemoglobin, which takes place after birth, is primarily the result of physiologic disintegration of the superabundant red blood cells carried over from fetal life in the presence of diminished erythropoiesis.

CEREBROSPINAL FLUID, Protein Values Determined by Tyrosine Equivalent Method, Marron, T. U. Am. J. Med. Sc. 202: 330, 1941.

Total proteins have been determined by the tyrosine equivalent method on 550 cerebrospinal fluids taken from persons in health and disease.

The upper limit of normal values has been found to be 46.0 mg. per 100 c.c. The ranges for pathologic values agree well with generally accepted figures in the literature.

The average protein values for females is less than that for males.

Dehydration does not appreciably affect the protein concentration.

TUBERCLE BACILLI, Demonstration of, by Fluorescence Microscopy, Richards, O. W., Kline, E. F., and Leach, R. E. Am. Rev. Tuberc. 44: 235, 1941.

Procedure:

1. Make direct smears of sputum, or of sputum concentrated on glass slides, and fix by heat in the usual manner.
2. Stain for two or three minutes with a solution of 0.3 per cent auramine in 3 per cent carbolic acid solution at room temperature.
3. Wash with water.
4. Decolorize with a solution of 0.5 per cent concentrated hydrochloric acid and 0.5 per cent sodium chloride in 70 per cent alcohol for one minute, pour off, and add fresh decolorizer for two additional minutes.
5. Rinse, dry, and examine.

Smears should be made preferably with fresh sputum. If a preservative is desirable, phenol will be more satisfactory than cresol, which reduces the number of organisms and causes an interfering fluorescence. Autoclaving will greatly reduce the number of organisms seen.

This staining technique is neither a painstaking nor a critical one. Almost any concentration of auramine will give the desired result; as little as 0.05 per cent of dye may be used. The concentration of phenol may be reduced. Satisfactory results have been

obtained with 0.5 per cent auramine in 2 per cent phenol. The stain originally recommended was 0.1 per cent auramine in 5 per cent phenol. The auramine is dissolved with gentle heat, but the stain becomes cloudy on cooling. Cloudy solutions are just as satisfactory as clear ones, but should be shaken just before use. The stain, after a number of weeks, gradually loses some of its fluorescent properties. Smears of known positive sputa should be stained and examined occasionally as a check on the keeping qualities of the dye.

Almost any of the standard decolorizing agents mentioned for decolorizing tubercle bacilli, such as 3 per cent hydrochloric acid, 5 per cent nitric acid, or even 25 per cent sulfuric acid, may be used. These stronger reagents require more careful timing; most of them decolorize in from twenty to thirty seconds. The slower, three-minute period decolorizer is recommended.

The newly designed equipment for fluorescence demonstration of acid-fast organisms has the following advantages over older methods for examining smears of sputum and other material for the presence of tubercle bacilli:

(a) The method stains more acid-fast bacteria than does the Ziehl-Neelsen technique.

(b) Examinations can be made with high dry objectives that cover fields which are larger than those covered by oil-immersion lens as well as being simple and more convenient for use.

(c) A greater contrast is obtained between the stained organism and other material present on the slide.

MONONUCLEOSIS, Infectious, Observations on, Warren, E. W. Am. J. Med. Sc. 201: 483, 1941.

The authors present evidence of the following phenomena to be found in infectious mononucleosis: Forssman heterophile antibodies are probably increased prior to the development of the heterophile antibodies of this disease and possibly are essential for their appearance. The typical lymphocytes of infectious mononucleosis are frequently found in disease entities in which a positive Paul-Bunnell has not been obtained. Only when the proportion of these abnormal cells is considerable does one find an elevated heterophile titer.

CL. WELCHII, Rapid Identification of, by the Nagler Reaction, Hayward, N. J. Brit. M. J., May 31, p. 811, 1941.

The production of a turbidity in human serum by the toxins of growing *Cl. welchii* (Nagler reaction) is a valuable aid to the rapid identification of the bacillus for diagnostic purposes. Excellent results are obtained with a mixture of equal parts of human serum and Fildes broth incubated anaerobically. The seeding of a single *Cl. welchii* colony into such a mixture produced a strong reaction in 80 per cent of the tests after one to two days' incubation. The reaction is specifically inhibited by antitoxin. Feeble reactions are not unequivocally indicative of *Cl. welchii*, since they are given by certain other species of anaerobic spore-bearer. Human serum-Fildes agar provides a means of detecting *Cl. welchii* on plates within twenty-four hours of taking a swab.

FUSOSPIROCHETOSIS, Recovery of the Causative Organism From the Blood, Williams, R. H. Arch. Int. Med. 68: 80, 1941.

The recovery of fusiform bacilli and spirochetes, of the type found in Vincent's angina, in cultures of the blood of 2 patients is recorded. *Fusospirochetes* were recovered eleven times from one patient and once from the other. Successful subcultures of the organism were made repeatedly. The organisms were slightly pathogenic for rats.

In the 2 patients fusospirochetemia was associated with an illness characterized by the sudden development of fever, prostration, headache, myalgia, and migratory arthritis. In one patient splenomegaly developed, with jaundice, a hemorrhagic eruption, and acute pleuritis. The source of infection is considered to be the tonsils in one instance and the bite of a rat in the other.

EOSINOPHILIA, Extreme, and Leucocytosis, Bass, M. H. *Am. J. Dis. Child.* 62: 68, 1911.

Three cases in which the disease was characterized by general adenopathy, leucocytosis, and extreme eosinophilia that occurred in childhood are reported.

In one case the patient had roentgenographic evidence of miliary pulmonary infiltrations, which persisted for several years but finally disappeared.

The leucocytosis, and especially the eosinophilia, remained long after the fever had disappeared. The course of the disease is chronic, but it may end in complete recovery.

In one case death occurred from intercurrent illness during the first year of observation. In the second case the patient was kept under observation for several years and finally recovered completely. In the third case, in which the patient is still being followed, there was a febrile period, but the child is now apparently in good health; the total leucocyte count has returned to normal, but a marked increase in eosinophilic cells still persists.

Data from 4 cases, reported from Havana, in which the disease resembled that in these cases are cited. The 7 cases resemble each other closely and appear to be examples of a clinical entity.

The relation of this syndrome to other pathologic states in which there are extreme leucocytosis and eosinophilia is discussed, and it is shown that the syndrome fails to fit into the category of any of the previously described conditions. Although the cause of the syndrome is unknown, it is most probably some type of chronic infection.

SULFANILAMIDE, Erythrocyte Fragility Changes Produced by, Antopol, W., Goldman, L., and Sampson, W. L. *Am. J. Med. Sc.* 202: 163, 1941.

The administration of sulfanilamide to rats results in an increased resistance of the red blood cells to hemolysis in hypotonic saline solution, and in splenomegaly with the histologic picture of active hyperemia such as seen in hemolytic anemia.

CORONARY ARTERY OCCLUSIONS, Incidence and Localization of, Schlesinger, M. J., and Zoll, P. M. *Arch. Path.* 32: 178, 1941.

More than one-half of the points of occlusion in the coronary arteries are overlooked by ordinary dissections.

Most zones of occlusion of the coronary arteries are less than 5 mm. in length and are, therefore, easily overlooked.

Occlusions are as numerous in the right coronary artery as in the left descending coronary artery.

There is no relationship between the manner of branching of the coronary arteries and the localization of occlusions therein.

The majority of coronary artery occlusions are found within 3 cm. of the mouths of these vessels.

ITEM

Urology Award

The American Urological Association offers an annual award "not to exceed \$500.00" for an essay (or essays) on the result of some specific clinical or laboratory research in urology. The amount of the prize is based on the merits of the work represented, and if the Committee on Scientific Research deem none of the offerings worthy, no award will be made. Competitors shall be limited to residents in urology in recognized hospitals and to urologists who have been in such specific practice for not more than five years.

Essays shall be in the hands of the Secretary, Dr. Clyde L. Deming, 789 Howard Avenue, New Haven, Conn., on or before April 1, 1942.

CLINICAL AND EXPERIMENTAL

SYSTEMIC HISTOPLASMOSIS*

SYSTEMIC HISTOPLASMOSIS DIAGNOSED BEFORE DEATH AND PRODUCED EXPERIMENTALLY IN GUINEA PIGS

J. D. REID, Sc.D., J. H. SCHERER, M.D., P. A. HERBUT, M.D., AND H. IRVING, M.T.
RICHMOND, VA.

THE discovery by Darling¹ in 1906 and the subsequent report of three cases of histoplasmosis in Panama has been followed by the observation of seven cases of this fatal systemic disease in this country. We are recording here the eighth case of systemic histoplasmosis that has occurred in the United States.† Diagnosis was made from the blood smear and blood culture during life. The disease in a systemic form also has been transmitted to guinea pigs for the first time.

Between the years 1906 and 1909 Darling² reported three cases of a systemic parasitic infection, the causative organism of which he named *Histoplasma capsulatum*. In each case diagnosis was made following autopsy, and Darling, because of the clinical picture and the resemblance of the parasites to Leishman-Donovan bodies, believed it to be a tropical disease related to kala azar. Not until 1926 was the next case recorded, and this by Riley and Watson,^{3, 4} was the first to be reported from North America. In the same year, Phelps and Mallory⁵ reported a case of "histoplasmosis of the lung," but neither the disease nor the pathology of this case resembled that of systemic histoplasmosis. A fifth case was found in an American negro in 1931 and was reported by Crumrine and Kessel.⁶ In all these cases the diagnosis was made only after autopsy, and attempts to culture the parasite were unsuccessful. Dodd and Tompkins⁷ dis-

*From the Departments of Bacteriology, Medicine, and Pathology, Medical College of Virginia.

†The report was written seven additional cases of systemic histoplasmosis have been reported. H. E. (Am. J. Trop. Med. 20: 603, 1940), reviewing the literature, records five cases, four of which appear to be systemic.

Received for publication, June 18, 1940.

covered in 1934 the sixth case in an infant from Tennessee. The diagnosis was made in this case for the first time during life by the finding of the parasites in the monocytes of the blood. For the first time, likewise, the organism was successfully cultivated from material obtained at autopsy, and DeMonbreun⁵ was able to produce the disease in monkeys by intravenous injection of cultures.

Subsequently, Agress and Gray,⁹ Amolseh and Wax,¹⁰ Shaffer, Shaul, and Mitchell,¹¹ and Clemens and Barnes,¹² reported cases of systemic histoplasmosis in which diagnosis was established at postmortem by the finding of the parasites within the cells of infected organs. Culture of the parasite from the spleen was obtained in only one of these four cases, that reported by Clemens and Barnes.¹²

Clinically, systemic histoplasmosis, as described by Darling, is characterized by "splenomegaly, emaciation, irregular pyrexia, leukopenia, and anemia." Only in the case of Crumrine and Kessel was splenomegaly absent. The pathology has been described as "the invasion of endothelial cells in the smaller lymph and blood vessels and capillaries by enormous numbers of a small encapsulated organism (*Histoplasma capsulatum*), causing necrosis of the liver with cirrhosis, splenomegaly, pseudogranuloma of the lungs, small and large intestines, with ulceration of the latter, and necrosis of the lymph nodes draining the injected viscera."¹³

CASE REPORT

The patient, a 38-year-old negro man, was referred to St. Philip Hospital, on March 23, 1939, for diagnosis. His chief complaint was "weakness," a symptom which had become progressively more pronounced since it was first noticed in mid-December. A janitor in a real estate office, he had continued at work until the day before admission, in spite of an increasing weakness of his arms and legs, which steadily increased the effort required in the performance of his routine duties. He had had a loose cough with slight expectoration since January, and had noted profuse sweating, associated at times with the sensation of "chills." The sweats were noticeable especially at night, often being of a severity sufficient to make him get up and change his clothing. For two months previous to his admission to the hospital he had been unable to walk more than a city block without sitting down to rest because of dyspnea and weakness in the knees. His appetite had grown progressively poorer, and during the last week he had drunk only milk. Hoarseness also had been noted during the last week. The patient believed he had lost about 50 pounds in weight, and for three weeks had been troubled with a watery diarrhea.

Past history was nonessential, except for the observation that the patient, born in South Carolina, had lived in Richmond, Va., for the past twenty years and had had no known contacts with the tropics. His health had been good until the present.

Physical Examination: The patient's skin was hot and moist. His mucous membranes were pale. He was very cooperative but a marked hoarseness made difficult his response to questioning. His temperature was 102° F., pulse rate 108, and respiration, 22 per minute. Examination of the eyes revealed small, white, irregular areas surrounded by hemorrhages in both fundi. These were not unlike tubercles. The pharynx was reddened. On laryngeal examination there was seen to be edema of both arytenoids with hyperemic cords which did not approximate well. The right cord especially was roughened, but there were no ulcerations. Lymph glands in the axillary, cervical, submental, and popliteal areas were enlarged, soft, discreet, and nontender. Chest examination revealed moist râles in both bases posteriorly and bronchial breathing on the right, anteriorly, just below the nipple area. With the exception of a soft systolic murmur, which was heard over the apex and not transmitted, heart examination was negative. The blood pressure was systolic 124 and diastolic 60. The abdomen was negative; neither the spleen nor the liver was palpated. There were no alterations in reflexes. The admission impressions were miliary tuberculosis, bacterial endocarditis, and Hodgkin's disease.

Laboratory Examination: Urinalysis: specific gravity 1.013, trace of albumin, occasional pus cell and hyaline cast. Blood: red cells 2,540,000; hemoglobin 54 per cent; white cells 3,200; differential count: neutrophils, 68 per cent, lymphocytes, 28 per cent, monocytes 4 per cent. Bleeding and clotting times were normal. Blood chemistry: sugar 141 mg., nonprotein nitrogen 25 mg., calcium 7.8 mg., phosphorus 3.1 mg., total protein 4.7 mg., albumin 2.1, and globulin 2.6. Complement fixation and flocculation tests were negative. Spinal fluid, stool, and agglutination examinations were also negative.

Röntgenologic examination of the chest showed "irregular mottling on the right first and second interspaces anteriorly with moderate density of the hilum and trunk shadows on the right, suggesting definite, minimal tuberculosis of the right lung."

In the hospital the patient ran a septic type of temperature which was characterized by an irregular regularity. This ranged between 100 and 103 degrees, rising to the higher level between 4 and 12 P.M. and falling during the night and early morning, only to rise again in the late afternoon or evening. This occurred daily without exception until the final week of his illness, when the temperature fluctuated between 99 and 101 degrees with the higher level still in the afternoon.

The patient continued to grow weaker, and, when repeated sputum examinations were negative for the tubercle bacillus, the hematologic service was consulted because of the anemia.

Study of the blood smear showed no malarial parasites. However, because of the presence of an endothelial type of monocyte, one of us (H. L.) continued to examine the smear further, the search being finally rewarded by the finding of a large phagocytic cell containing numerous small bluish hyaline bodies which, at the time, were not identified. The report on this examination was: "Blood smear shows slightly regenerative, hypochromic, microcytic anemia with rare normoblasts. There is a left shift at the stab level and the neutrophils show slight toxic granulation with frequent Döhle bodies. An occasional 'blast' cell is seen and the platelets appear greatly reduced. On checking, these were found to number 122,000 (normal 500,000). Phagocytic monocytes are present and rarely one of these is seen to contain numerous small bluish hyaline bodies with dark staining nuclei. These measure 2μ to 4μ and vaguely resemble Leishman-Donovan bodies."

Sternal puncture was resorted to for further study of the blood. The bone marrow aspiration showed numerous monocytes filled with the parasites, and there were numbers of neutrophils containing from one to five organisms. The marrow was moderately erythroblastic and contained a number of plasma cells. Megakaryocytes were notably decreased. In addition to the parasites there were phagocytosed red and white blood cells in the large endothelial cells, many of which were binucleated.

Following this finding, an axillary lymph node was removed. This showed a chronic lymphadenitis with proliferation of the reticulum, the reticulum cells, under oil immersion, being engorged with numerous inclusion bodies which possessed a pale peripheral halo and a faint oval basophilic center.

A previously negative blood culture was re-examined and a fresh culture was taken. These were examined for fungi and found to be positive for *Histoplasma capsulatum*. In the meanwhile daily blood smears continued to show the parasites in increasing numbers. While at first the parasites had been observed only in the monocytes, as the disease progressed the neutrophils were found to contain them. There was a steady increase in toxic degenerative granulation of the leucocytes, as normoblasts and myelocytes began to appear in greater numbers, and the patient, becoming gradually weaker, died in stupor on April 24, 1939.

POST-MORTEM EXAMINATION

(Abstract from Protocol)

Externally the only finding of interest was that of a moderate swelling of lymph nodes in the axilla, groin, and neck. No skin lesions of any type were noted.

Thorax: The right pleural cavity contained approximately 500 c.c. of clear straw-colored fluid. There was no effusion into the left pleural cavity or the pericardial cavity.

Lungs: The base of the right upper lobe in its lateral aspect showed a depressed stellate grayish-white area, measuring approximately 0.5 cm. in diameter in its central portion. Sections through this lesion showed a roughly triangular area slightly raised, measur-

ing about 2 cm. at its pleural base and 3 cm. from the base to its apex near the hilus. This area of infiltration was composed of discrete and frequently conglomerate nodules, measuring from the size of a millet seed to 3 mm. in diameter. They were situated for the most part peribronchially, but did not show rosette formation or any other distinct pattern of distribution. On cut surface the nodules were raised, grayish white in color and partially caseous in their center. The margins of the larger confluent areas of grayish-yellow necroses were firmer and presented a somewhat gritty sensation when scraped with a knife. The intervening tissue was slightly depressed beneath the cut surface with grayish-white prominent bands. There was abundant anthracosis in this area. No abscesses were seen. The remaining parenchyma of both lungs was normal. The hilar lymph nodes were moderately enlarged and contained carbon pigment; they failed to disclose distinctly visible nodules or areas of caseation.

Spleen: The spleen weighed 500 Gm. and measured 11 by 11 by 7 cm. It was firmer in consistency than normal. The pulp did not scrape away on the knife edge. The follicular and trabecular structures were obscured.

Kidneys: Each kidney weighed 200 Gm. and measured 10 by 7 by 4 cm. Their surfaces were very finely granular. The cut surface was very moist. There was an eversion of the cut edges. The corticomedullary demarcations were markedly obscured. The architecture of the medulla and cortex proper appeared to be normal.

Liver: The liver weighed 2,400 Gm. Its dimensions were 27 by 18 by 10 cm. Grossly it presented no abnormalities.

Intestines: The lower 45 cm. of the ileum, the cecum, and the ascending colon showed scattered mucosal nodules, measuring from 2 to 5 mm. in diameter, raised about 2 mm. above the surface. The smaller nodules were grayish white. On sectioning they were firm and solid. The larger ones showed central areas of caseation. In the cecum and ascending colon were found numerous areas of ulceration, mostly round in shape. Their margins were sharp but ragged and surrounded by a hemorrhagic zone. They did not seem to be undetermined. The ulcers measured from 1 mm. to about 5 mm. in diameter.

Lymph Nodes: The mesenteric lymph nodes were moderately enlarged. The para-aortic lymph nodes and lymph nodes of the liver hilus were markedly enlarged, matted together in irregular masses adherent to the adjacent tissues. They were firm to palpation and on section showed irregular well-defined areas of yellowish necrosis.

Vertebral Bone Marrow: Showed grossly no abnormalities.

MICROSCOPIC EXAMINATION

Organisms: Characteristic organisms of *Histoplasma capsulatum* were found in the lungs, spleen, kidney, intestines, liver, pancreas, lymph nodes, and bone marrow. The organism itself was usually round, or slightly oblong, in shape, and measured approximately 2μ to 4μ in diameter. In both the ordinary hematoxylin-eosin stain and in Goodpasture's stain the external membrane was nonstaining and doubly refractile. The internal structure of the organism was variable. It contained a clear vacuolated nonstaining cytoplasm and a bluish-stained chromatin material, the arrangement of which varied greatly. In some of them the chromatin material was finely granular and found in the center of the body; in some it was situated at one or both poles in the form of small and larger round masses; in others these unipolar or bipolar masses were more crescentic in shape and partially encircled either one or both poles. In still others they seemed to encircle the periphery entirely. In all bodies the remaining portion of the organism was composed of a nonstaining cytoplasm which was negative for both Ziehl-Neelsen and fat stains. For the most part the organisms were found ingested in cells, but occasionally they were found free, singly and in groups.

Typical Lesion: The typical lesion produced in the various organs by *Histoplasma capsulatum* was a rather characteristic nodular granuloma resembling a tubercle or a gumma. The nodules varied in size from 15μ to 20μ to several millimeters in diameter. The smaller were circular in outline, the larger appeared to be confluent, disclosing serpiginous borders or a maplike outline. The central portions were composed of eosinophilic staining, partially granular, unidentifiable material. Some foci of necrosis contained many nuclear fragments.

In many of them, this central area of necrosis still revealed a shadowy outline of the underlying structures. Capillaries were found to be coursing through the entire nodule and were often seen to be patent and filled with blood, even in the center of the necrosis. The central necrotic areas frequently disclosed the structure of elastic membranes still completely or partially intact. The alveolar septa and vessels could easily be recognized within the areas of necrosis by elastic tissue stains. At the periphery the necrotic areas shaped themselves into ill-defined faintly staining "ghosts" of markedly engorged mononuclear cells. Still more peripherally the large monocytes were well preserved. They contained ingested material which was composed of large numbers of closely packed *Histoplasma capsulatum* organisms. About the periphery of the nodules were scattered plasma cells, lymphocytes, and a few polymorphonuclear cells. Giant cells and epithelioid cells were absent.

Fig. 5.—Yeastlike forms of *Histoplasma capsulatum* from a six-day-old culture on sealed blood agar slant at 37° C. Wet mount (X700).

Fig. 6.—Hyphae developing from yeastlike form in semisolid culture media containing fresh blood at 37° C. Wet mount (X700).

Lungs: Sections through the lesions at the base of the upper lobe of the right lung showed many of the typical granulomas described. Here they were mostly confluent. In one area a cytoplasmic mass was encountered which resembled a Langhans' giant cell: vesicular nuclei were grouped around a pink-staining cytoplasm. It could not, however, be definitely identified as a foreign body giant cell. In addition to the above-described typical lesion there was a marked polymorphonuclear cell infiltration in a diffuse form in the

Fig. 7.—Early mycelial type of growth in same media as Fig. 6 at room temperature. Wet mount ($\times 700$).

Fig. 8.—Development of mycelial form on dextrose agar plates at room temperature, showing enlarging arthrospores. Wet mount ($\times 700$).

Fig. 9.—Further development of arthrospores showing the tuberclelike protrusions. Wet mount ($\times 700$).

interalveolar septa. There were also discrete areas of dense infiltration with polymorphonuclear cells, which showed a liquefactive necrosis of the underlying tissues. These possessed all the characteristics of a true, though small, abscess. Marked interstitial infiltration with lymphocytes and plasma cells was found in the vicinity of the above-described granulomatous nodules in the interalveolar septa. There was extensive fibrous scarring throughout. A number of large discrete areas were encountered which resembled old-healed conglomerate tubercles. In fact, from a histologic point of view, they could not be distinguished from the latter. It is uncertain whether or not such foci should be looked upon as a healing phase of the granulomas caused by *Histoplasma capsulatum*.

Vessels were involved in the inflammatory processes. Arteries of various sizes were seen with proliferating endarteritis and complete obstruction of their lumina. The granulation tissue in many areas involved medium-sized and smaller veins. Elastic tissue stain disclosed that all layers of the wall were infiltrated by a variety of small round cells. The elastic lamellae, in particular those of the adventitial layers, were "teased up," split apart, and partially disintegrated. The process encroached upon the media and resulted in disintegration of the wall and segmental disappearance of elastic fibers. Many veins showed proliferation of subintimal cells with formation of intimal pads. In some of these the granulation tissue completely occluded the lumen.

Fig. 10.—Three weeks' old culture on Sabouraud's dextrose agar at room temperature. The aerial hyphae which give the colony its fluffy appearance are plainly visible. Wet mount ($\times 0.5$).

Spleen: The spleen showed many minute discrete nodules of the typical type. Polymorphonuclear cell reaction, however, within or in the vicinity of these granulomas was rather scarce. The sinusoids were dilated and contained large monocytes and desquamated reticulum cells, both of which were markedly engorged with organisms. There was diffuse hyperplasia of the reticulum which was best seen in silver stains.

Pancreas: The pancreas showed a slight diffuse lymphocytic and plasma cell infiltration of the somewhat edematous interstitial connective tissue. There were also scattered macrophages that contained the ingested organisms. Characteristic nodules were not encountered.

Kidneys: The kidneys did not show specific nodules. The organisms, however, were occasionally found in large cells in the glomerular tufts. It could not be determined whether these cells were endothelial or epithelial. The interstitial tissue of the cortex showed edema and a moderate infiltration with plasma and round cells. Occasional polymorphonuclear cells were also encountered.

Liver: The liver contained many minute and larger typical *Histoplasma capsulatum* nodules. They bore no special relation to the liver lobules, some being found in the portal areas, others midway between the center and the periphery of the lobules, and still others

occupying most of the lobule. In addition, Kupffer cells throughout the entire liver substance were greatly increased in size and contained the organisms. Otherwise the liver was essentially negative.

Intestines: The ulcers about the ileocecal region were rather superficial, and, as a rule, did not extend deeper than the *submucosa*. The edges were rather sharp, not undermined. The floor and margins were composed of necrotic tissue with nuclear fragments and "ghosts" of large mononuclear cells with phagocytosed organisms. Beneath the floor was found a layer of nonspecific granulation tissue that contained many mononuclear macrophages with ingested organisms, a variety of larger and smaller round cells, fibroblasts, and capillaries. Polymorphonuclear cells were found abundantly within this granulation tissue. The involvement of the vessels was of the same type as that described in the lungs.

Lymph Nodes: They contained many typical granulomas already described. Reticulum cells throughout were very conspicuous, being greatly engorged with organisms. The follicles were small and widely separated by diffuse hyperplastic reticulum. Polymorphonuclear cells were scarce. Many veins in the periphery were engorged with macrophages that contained the organisms. Periendophlebitis, as described in the lung, was likewise encountered in the vicinity of the caseous granulomas.

Bone Marrow: Rather actively functioning, the bone marrow contained numerous large mononuclear macrophages and reticulum cells engorged with the organisms.

Brain: Permission for examination of the brain was not given, and it was, therefore, not possible to examine the eyes.

The remaining organs of the body were essentially negative.

MYCOLOGIC STUDIES

The clinical symptoms of histoplasmosis are so ill-defined that only one of the ten cases published previously has been diagnosed before the death of the patient. In this case, presented by Dodd and Tompkins,⁷ the typical yeastlike bodies of *Histoplasma capsulatum* were found in the smears of the blood. Later, the fungus was also cultivated from the blood by DeMonbreun.⁸ Clemens and Barnes¹² have also reported finding the parasite in a blood culture taken on their case and examined one month later after diagnosis was established at autopsy. Since the ante-mortem diagnosis of this infection rests, at the present time, upon these findings, we are presenting the cultural methods used in obtaining the parasite from this case of systemic histoplasmosis.

The blood culture media utilized for routine work in the laboratory and which we used in this study is prepared as follows: Veal infusion broth containing 0.3 per cent dextrose, 0.5 per cent sodium citrate, and 0.2 per cent agar adjusted to pH 7.4 is sterilized in 40 c.c. amounts in small Erlenmeyer flasks. Usually 10 c.c. of blood are taken from the patient and inoculated directly into the flask. Incubation is carried out aerobically or anaerobically, as the case may warrant, at a temperature of 37° C.

The first blood culture was received from the patient four days after admission to the hospital, and approximately fourteen weeks after the onset of symptoms. This culture was found to be contaminated and was discarded at the end of four days' incubation. A second blood culture was received three days later. There were noticed in this flask at the end of twelve days' incubation numerous yeastlike bodies and a few scattered mycelial threads. One of us (H. I.) had found similar bodies somewhat earlier in smears prepared from the peripheral blood. These bodies were always found within the cells, particularly within the cytoplasm of the large monocytes. The yeastlike cells in the blood culture media tended to adhere to one another after division and were

often found in small clusters, particularly in wet preparations. One or two dark granules were visible within the otherwise clear cytoplasm of these unstained cells. When stained by Wright's method, the organisms were almost identical in appearance to those occurring in the tissue cells. They appeared as oval, occasionally round, cells, 2.7μ to 3.6μ in their longest diameter, exclusive of the capsule surrounding them. In this respect they were slightly larger than the parasites within the cells, the majority of which were between 1.8μ and 2.7μ , although infrequently larger cells measuring up to 3.6μ could be found. Within the parasite was a dark staining chromatin-like mass placed either at the larger end or in a semilunar arrangement at the end and along the side walls of the cells.

On the same day that this finding was made, a third specimen of blood was taken in citrate solution. When this was cultivated on Sabouraud's dextrose agar plates, fungi again were isolated.

Subcultures of the first blood culture showing growth were made in duplicate on Sabouraud's dextrose agar, dextrose extract agar, brain veal agar, and sealed brain veal blood agar slants. One set of slants was incubated at 37°C . and the other set at room temperature. Growth first appeared in the subcultures on Sabouraud's dextrose agar and dextrose extract agar kept at room temperature. Within five to six days small white colonies with a downy surface were visible. They slowly increased in size, with the production of white, feathery, aerial hyphae, arising from a base which became brown in color as the colony aged. The colonies adhered tenaciously to the surface of the media and were removed with difficulty. Similarly growth appeared on the plain brain veal agar slightly later, but at no time was growth on this media as heavy or as rapid as that on media containing dextrose.

Wet preparations of material from these colonies showed branched, hyaline, septate mycelium, 2μ to 5μ in diameter, within which were seen many dark, dancing granules. Developing arthrospores, 8μ to 13μ in diameter, were visible. They occurred on the ends of branches or from stalks along the hyphae. These smooth-walled spores also contained numerous sporelike bodies which Moore¹⁴ considered to be endospores. The studies of Howell¹⁵ have shown these larger cells to be true aleurospores. Occasionally in old cultures one could see tuberculate spores, pyriform in shape.

On sealed blood agar slants and in semisolid culture media containing fresh blood incubated at 37°C . the tendency was for the fungus to grow in the yeastlike stage. Cells somewhat larger than those seen in the tissues formed. These observations were similar to those of DeMonbreun,⁸ who first determined the two forms of growth for this organism. The first, the yeastlike form, occurs in the body and on blood agar slants. He used the growth from these slants to reproduce the disease experimentally in monkeys. The second, the mycelial stage that we have described above, occurs on media incubated aerobically at room temperature. Intermingled with the yeastlike forms were larger cells from which hyphae appeared to be developing. The gross appearance of the growth on sealed blood agar slants was that of dull, grayish-yellow colonies, adhering well to the media. The surface of the colonies was smooth with slight tendency to the formation of aerial hyphae.

PRELIMINARY ANIMAL EXPERIMENTS

Mice. Ten mice were inoculated intraperitoneally with amounts varying from 0.5 c.c. to 1.0 c.c. of a saline suspension of the six days' growth from the sealed blood agar slants. Although there was some indication of infection in two mice, the results with these animals were unsatisfactory, perhaps due to their relative insusceptibility to infection with the fungus.

Rabbits. Two rabbits were injected intravenously with 1.5 c.c. each of a similar suspension to that used in mice. Seven weeks later the animals were killed and autopsied. The organs were normal on gross appearance. Smears prepared from various tissues failed to show the *Histoplasma capsulatum* bodies.

Guinea pigs. One guinea pig was inoculated intraperitoneally with 1.0 c.c. of the original growth in the blood culture media. This culture had been incubated for two weeks at the time it was used for the animal inoculation. The pig gradually lost weight, and at the end of seven weeks was greatly emaciated. It was killed at this time and examined for evidence of infection. Lesions typical of those found in histoplasmosis were present.

There was a collection of fluid in both the peritoneal and pleural cavities. The spleen was enlarged to approximately three times its normal size. The inguinal lymph nodes were enlarged. The lesions in the lung partially involved the pleura and gave rise to a local fibrinous pleuritis. Smears made from the peritoneal fluid, spleen, lymph nodes, lungs, liver, and bone marrow showed many histoplasma bodies present both free and within the cells.

Histologic examination. Small granulomas were seen in the lungs, liver, and spleen. *Histoplasma capsulatum* organisms were noted in these organs and also in the lymph nodes and bone marrow. The lesion was essentially similar to that described in the patient.

Histoplasma capsulatum was grown from tissue taken from the lungs, spleen, and lymph nodes.

COMMENT

The hematologic aspects of our case are of particular interest, for if the diagnosis is to be made before autopsy it must be from a study of the blood and blood culture. Once one has seen these large, vacuolated endothelial phagocytes with wavy, pale staining, light blue cytoplasm engulfing numbers of the parasites, one should be able to recognize them thereafter without difficulty. The disease may be more common than has been supposed, and the finding of an anemia with leucopenia in a weakened, emaciated patient who is found to have a septic temperature should lead one to search the blood smear for these parasitic-laden monocytes.

Presence of the *Histoplasma capsulatum* in the neutrophils has not been noted in other cases reported. In the terminal phase these were noted in increasing numbers, the polymorphonuclear cells containing from one to five parasites. The further observation that the organisms, as in kala-azar and malaria, appear in great numbers in the bone marrow makes sternal puncture valuable as a diagnostic approach in suggestive cases.

The stage of the disease in which the parasite may first be found in the blood in human beings is not at present known. As sternal puncture, performed the

same day the organism was found in the blood only after prolonged search, showed parasites in the bone marrow in great numbers, this should prove a valuable aid in early diagnosis. Blood culture at this time also was positive.

Fig. 11.—*Histoplasma capsulatum* organism in an endothelial cell in a glomerulus of the kidney ($\times 2,500$).

Fig. 12.—Large tubercle-like granuloma in the lung ($\times 25$).

Dodd and Tompkins⁷ felt that the anemia of histoplasmosis was to be attributed in part to the phagocytosis of red blood cells. While phagocytosis must undoubtedly play a part, the leuco-erythroblastic type of blood smear and the numbers of large monocytes found in the bone marrow would suggest

that the anemia is largely due to crowding of the marrow by numbers of these large monocytes.

The tubercle-like lesions with hemorrhage in the fundi have not been noted in the other reported cases. It is unfortunate that post-mortem verification of these lesions was not possible.

Fig. 13.—Elastic tissue stain, lung. Granulation tissue breaking through the wall producing subintimal proliferation ($\times 150$).

Fig. 14.—Alveoli of the lung containing large endothelial cells filled with the parasites ($\times 360$).

Histoplasma capsulatum can be grown with comparative ease on a variety of media, using either fresh or citrated blood from the patient. However, flasks of liquid or semisolid media, such as we have used, are most desirable because of the larger amounts of blood that can be inoculated.

Initial growth is slow in the blood culture media incubated at 37° C. The yeastlike forms that develop under these conditions may not be numerous enough to be easily seen in wet mounts or stained preparations until one or two weeks have elapsed. When stained by Wright's method, the young cells are in appearance very similar to those seen in blood smears from the patient. The dark staining chromatin mass within the cells lies either at the end or along the side walls. Many cells are surrounded by a clear capsular-like area.

The vegetative form of the fungus develops when these cells are subcultured on solid media and incubated at room temperature. Growth occurs more rapidly than in the initial isolation and may be visible within five to six days as small, white, downy colonies. This type of growth is characterized by the formation of large, tuberculate spores which are an aid in identifying this and related species and may be seen in wet mounts of the colonies. They have been likened in appearance by DeMonbreun⁸ "to the ancient Teutonic war clubs."

No previous report of the reproduction of systemic disease in guinea pigs has been noted. We have successfully infected this animal by intraperitoneal injection of the yeastlike form. A slowly progressive infection was produced, and at autopsy the typical pathology of histoplasmosis was observed.

Thus far, our attempts to reproduce the disease in mice and rabbits have not been successful.

It is interesting to note that the parasite was seen at autopsy in the kidneys of both the patient and the experimentally infected animal. This offers the future possibility of isolating the organism from the urine. Preliminary experiments with guinea pigs, which will be reported later, bear out this suggestion. We have been able to isolate the organism from this source on several occasions.

Frequently the lesions found at autopsy have been compared with the tubercle. Though the foci vary to a certain extent in various organs according to the stage of development, they differ essentially from the tuberculous lesion in that true epithelioid cells and Langhans' giant cells are absent. The large mononuclear cell reaction in some areas may closely resemble epithelioid cells of an early tubercle, but parallel arrangement in radiating fashion, elongation to spindle-shaped cells, and a resemblance to endothelial or connective tissue elements could nowhere be demonstrated. Furthermore, the lesions of the lung differ essentially from the formation of tubercles in that the tissue undergoes necrosis apparently before proliferative reaction has commenced. The areas of necrosis in contradistinction to tuberculosis show the shadowy outline of the underlying structure and the intact vessels traversing the foci.

The involvement of vessels is a conspicuous feature, particularly the periendothelitis, though this process is not in itself pathognomonic. It has been suggested by Phelps and Mallory,⁵ and later by Dodd and Tompkins,⁷ that the packing of blood capillaries and sinusoids with leucocytes causes the focal necrosis by ischemia. It is our impression that some toxic process liberated by the organism is responsible for the necrosis, since small vessels and capillaries are abundant and patent, both surrounding the nodular granuloma and even passing through the necrotic areas.

The appearance of the healing stage of the nodular granulomas found in the lung has not yet been described satisfactorily. It is uncertain in our mind

whether the nodules in our case resembling old healed tubercles should be interpreted as healing *Histoplasma capsulatum* granulomas or true tubercles. Finally, it should be mentioned that marked polymorphonuclear cell reaction with abscess formation occurs. This type of cellular reaction has not been described in any other previous case.

SUMMARY

A case of systemic histoplasmosis is reported in which diagnosis was made before death by means of smear and culture of the organism from the blood.

Experimental production of the disease in guinea pigs is described.

A detailed description of the pathologic morphology and its differential diagnosis is given.

THE PATHOLOGY OF ATROPHIC ARTHRITIS*

A CORRELATED CLINICAL AND LABORATORY STUDY

CHARLES LEROY STEINBERG, B.S., M.D., ROCHESTER, N. Y.

THE soft and hard tissue changes which take place in rheumatoid or atrophic arthritis proceed in a certain sequence. The swelling, the increase in local heat, and redness of the soft tissues of the joint structure which the clinician observes, and the pain and stiffness of the joints which the patient notices are caused by an active inflammation of the synovial membrane, the capsule, and the surrounding soft tissue structures of the joint. The synovial membrane or stratum synoviale is normally made up of a thin layer of cells richly supplied with nuclei and a subjacent area of connective tissue cells poorly supplied with nuclei. The synovial membrane is richly supplied by a close network of blood vessels and nerves. Fig. 1 is a photomicrograph through normal synovial membrane. In atrophic arthritis there is marked proliferation of the cells of the synovial membrane which eventually produces a layer of granulation tissue or pannus over the articular cartilage. A similar process occurs simultaneously, involving the connective tissue elements of the marrow below the articular cartilage. The latter process extends through the zone of provisional calcification and destroys the articular cartilage from below, while a similar pathologic process evidenced by the proliferated synovial membrane destroys the articular cartilaginous surface. These two opposing processes eventually destroy the articular cartilage. These two layers of active granulation tissue have marked potentialities of forming fibrous and bony tissues, and when they do we have a resulting fibrous or bony ankylosis.

The synovial fluid is increased in the earlier stages and decreased in amount or completely absent in the later stages. Round cell infiltration occurs into the capsule, new blood vessels appear, and fibroblastic activity occurs. Decalcification occurs in the juxtaarticular position. This leads to rarefaction and loss of density. The pathologic picture given so far is essentially in agreement with that given by Nichols and Richardson,¹ Allison and Ghormley,² and others.³ Allison and Ghormley² believe that atrophic arthritis has a specific micro-pathology. "Histologically the tissue shows a definite picture, it is as clear-cut as is that of tuberculosis, mainly a proliferative change in the synovial membrane and marrow which is characterized by focal collection of lymphocytes. This microscopic picture will, we believe, be enough to establish the diagnosis of proliferative arthritis, and in our own experience has been enough to predict the subsequent changes in several instances where the tissues showed the character-

*From the Arthritic Clinic, Rochester General Hospital, Rochester, N. Y.
Presented by title at the Seventh Annual Meeting of the American Rheumatism Association, New York City, June 10, 1940.
Received for publication, November 13, 1940.

istic changes in the early stages of the clinical disturbances." They emphasize that the focal collections of lymphocytes are not perivascular. Miller⁴ adds to this interpretation. He believes that the focal collection of lymphocytes indicates that atrophic arthritis is an inflammatory disease of bacterial origin.

In 1929 Fisher⁵ described a histologic picture in atrophic arthritis in which there was perivascular round cell infiltration. Parker and Keefer⁶ have recently written an excellent article on the pathologic changes in three cases of atrophic arthritis in which they described the microscopic picture in some regions as showing collections of round cells which were perivascular, as described by Fisher⁵ in 1929, and in other regions in which the focal collection of lymphocytes was not perivascular, as described by Allison and Ghormley² in 1931. These authors failed to give clinical histories in two of these cases. Such a correlated study would have added to the value of their report. Boyd⁷ states that the arteries in the surrounding tissue of the diseased process in atrophic arthritis often show an obliterating arteritis and deposits of fibrin under the endothelium. This vascular change in atrophic arthritis is not mentioned in the other articles previously cited.

Fig. 1.—A high-power photomicrograph through normal synovial membrane. Note the lining layer of epithelial-like cells and the adjacent layer of connective tissue.

The philosopher Friedrich Nietzsche, who lived in the latter part of the nineteenth century, in his apophthegms and interludes stated, "Everything absolute belongs to pathology." And so it is. In a protean disease, such as atrophic arthritis, which is characterized clinically by remissions and exacerbations, whose onset may be acute or may be quite gradual; which may attack the young, the middle aged, and the aged; which may deform in a very short time, or else may continue in a mild course for many years, one should find different gross and microscopic pathologic findings depending upon the time in which the disease was studied, perhaps the grade of the disease, and the duration of the disease in that particular individual. I have taken case histories of various grades and durations of atrophic arthritis and correlated these with the microscopic pathologic picture to be found in that particular case. It is hoped from this unbiased report that the controversial issues of the pathologic picture of atrophic arthritis may be clarified to some extent.

CASE REPORTS

CASE 1.—L. G., a white female, aged 60 years, was first seen on April 8, 1935. She complained of painful, swollen stiff joints. She had not been able to get out of her bed for a period of several months due to crippling because of this condition. The onset of her joint trouble began in 1902, with pain and swelling of the proximal interphalangeal joints of both hands. The condition had slowly progressed until it involved practically all the joints. There was a history of two severe flare-ups, one in 1923 and one in 1933. During

Fig. 2A.—A low-power photomicrograph showing a villous mass made up of proliferative synovial tissue in advanced atrophic arthritis.

Fig. 2B.—A high-power photomicrograph of the same case showing the marked increase in fibroblasts characteristic of the "healed" or "burnt out" case of atrophic arthritis.

this period of thirty-one years most joints of the body had become involved with pain, swelling, and redness. The examination of the joints on April 8, 1935, revealed little motion in the finger joints, soft tissue swelling of the metacarpophalangeal joints with wasting of the interossei group of muscles, marked limitation of pronation and supination in the elbow olecranon bursa. Both the knee joints were swollen, and there was marked increase thickness of the capsule. Thirty degrees flexion deformity was present in both knees. The ankles were also swollen and quite tender. Blood pressure was systolic 120 and diastolic 80. Lab.

oratory examination revealed a sedimentation rate of 1.00 and a negative Wassermann test. The diagnosis was advanced atrophic arthritis. The patient was treated with bed rest, moist heat to the joints, massage, high caloric diet, and hemolytic streptococcal vaccine. The arthritic process quieted down after two months' treatment. A right synovectomy was done on June 14, 1935. There was marked increase in fluid in the joint, extensive arborescent villous growth, and marked destruction of the cartilage. Microscopic sections of the synovial membrane removed from this joint are shown in Figs. 2*A* and 2*B*. One is a low-power

Fig. 3*A*.—A low-power photomicrograph showing a focal collection of lymphocytes, increase in capillaries, and in fibroblasts.

Fig. 3*B*.—A high-power photomicrograph of the same case showing a diffuse round cell rather than a perivascular round cell infiltration.

and the other is a high-power photomicrograph of this tissue. These sections show marked increase in granulation tissue and areas of hyalinization. There is also diffuse marked increase in round cell infiltration. The high-power photomicrograph particularly shows the increase in fibroblastic activity and the decrease in cellular infiltration. Cultures from the joint and guinea pig inoculation were negative. The pathologic picture in this case was typical of a chronic advanced atrophic arthritis. The marked proliferation of synovial tissue, as evidenced by the villous growth and the replacement of the synovial tissue by fibroblasts and the relative absence of lymphocytes in the synovial membrane in this case, represents the so-called "healed" type or "burnt out" case.

CASE 2.—C. N. H., a white female, aged 47 years, was first seen in February, 1938, complaining of pain and swelling and limitation of motion of the right knee of one month duration. The blood pressure was systolic 120 and diastolic 85. Examination of the right knee revealed diffuse swelling and moderate tenderness of the joint. There was little limitation in motion of this joint. A synovectomy was done, and section through the synovial membrane revealed the so-called typical focal collection of lymphocytes, as described by Allison and Ghormley,² increase in fibroblastic activity, and increase in the number of capillaries (Fig. 3A). Culture from the joint and guinea pig inoculation were negative. The high-power photomicrograph of this tissue definitely reveals the absence of perivascular round cell infiltration (Fig. 3B).

Fig. 4.—A photomicrograph through a blood vessel of the synovial membrane in a case of atrophic and hypertrophic arthritis complicated by essential hypertension and syphilis.

CASE 3.—H. B., a white female, 54 years of age was first seen on July, 1938, complaining of a painful swollen right knee of ten months' duration. Examination of the joint revealed moderate swelling of both joints. An x-ray examination revealed evidence of hypertrophic arthritis as evidenced by new bone production. The blood pressure was systolic 240 and diastolic 118. The patient was a known syphilitic who had been treated for syphilis for five continuous years up until one year before the present observation. Her last Wassermann test was minus, 3 plus, 3 plus. A section through a blood vessel of the synovial membrane of the right knee is shown in photomicrograph Fig. 4. The marked increase in thickness of the muscular wall may be due to the hypertension. The fibrinous exudate in the lumen of the vessel may be due to the syphilitic process. This case emphasizes the need of correlated clinical and pathologic study before conclusions as to the exact pathology of atrophic arthritis are made.

CASE 4.—S. M., a white female, aged 27 years, gave a history of one year's duration of painful swollen joints. The patient first noticed pain and swelling in the smaller articulations, but this gradually progressed until most joints of the body had become involved. She had noticed definite flare-ups associated with upper respiratory infections. The physical examination revealed a well-developed, but poorly nourished, white female. Her tonsils had been removed, and the dental examination both on physical and by radiographic examinations were negative. The posterior pharynx appeared moderately injected. Vaginal examination revealed the patient to be a virgin. Examination of the joints revealed the following: Marked limitation of motion of the right wrist and finger joints; a swollen, inflamed, and quite tender, right knee. Laboratory examination: Sedimentation rate on November 30, 1936, 1.10; serum calcium 11.3; serum phosphorus 4.5; Wassermann reaction negative. Throat

culture revealed both hemolytic streptococci and *Streptococcus viridans*. Vaginal smear and culture were negative. The patient was treated with bed rest, high caloric diet, moist heat, and hemolytic streptococcal vaccine. The sedimentation rate on December 21, 1936, was 0.88. Laboratory examination on January 4, 1937, revealed a sedimentation rate of 0.91, a negative complement fixation test for the gonococcus, a basal metabolism minus 1 per cent; throat culture was negative for hemolytic streptococci. X-ray examination of the joints revealed a negative examination as regards bone structure of the left knee. There was slight narrowing of the joint spaces of the temporomandibular joints. X-ray examination of the right knee on September 16, 1937, was no longer normal. There was roughening of the spine of the tibia, roughening of the joint surface, particularly the lateral aspect.

Fig. 5A.—A low-power photomicrograph through the synovial membrane of case S.M. showing both polymorphonuclear and round cell infiltration.

Fig. 5B.—A high-power photomicrograph through the same tissue showing the "purulent" inflammatory reaction characterized by the polymorphonuclear infiltration.

There was also questionable narrowing of the joint space. Both knees and the left ankle were markedly swollen, and there was definite increase in local temperature on January 13, 1938. The sedimentation rate at this examination was 1.53. The patient was treated at home by bed rest, hot baths, general massage, high caloric diet, and hemolytic streptococcal vaccine until November 14, 1938. She had shown marked clinical improvement during this

Fig. 6A.—A very low-power photomicrograph through the entire synovial membrane removed from the left knee of case S.M. This shows diffuse round cell infiltration of the entire layer, most pronounced near the surface.

Fig. 6B.—A high-power photomicrograph through the surface layer of case S.M. showing marked round cell infiltration.

Fig. 6C.—A high-power photomicrograph through the synovial membrane of case S.M. showing diffuse round cell infiltration and increased fibroblastic activity.

period, and it was deemed advisable to do a bilateral synovectomy. A right synovectomy was done on November 21, 1938. Figs. 5 and 5.1 are sections through the synovial membrane removed from the right knee during this operation. Fig. 5.1 is a low-power photomicrograph, and Fig. 5B is a high-power photomicrograph. The most striking feature is the presence of polymorphonuclear cells throughout the membrane. In fact, the synovial membrane is much fibrosed, and the inner layer showed a purulent inflammatory reaction, a finding much more common in typical pyogenic arthritis than in atrophic arthritis. The patient made an uneventful recovery, and a synovectomy was done on the left knee on December 14, 1938. Figs. 6A, 6B, 6C, and 6D are sections through the synovial membrane removed from this knee joint. Fig. 6A is a very low-power photomicrograph, and Figs. 6B and 6C are high-power photomicrographs. The inner surface of this synovial membrane showed much fibrosis and very marked infiltration of the round cells. This round cell infiltration was diffuse. Fig. 6C is a section through the synovial membrane removed from the left knee; it shows definitely that the round cell infiltration is not perivascular. Fig. 6D, a very high-power photomicrograph of another section through the same synovial layer, showed a blood vessel with definite perivascular round cell infiltration.

Fig. 6D.—A very high-power photomicrograph taken through another area of the synovial membrane in case S.M. showing perivascular round cell infiltration.

COMMENT

No specific micropathology exists in chronic atrophic arthritis. The disease is characterized by remissions and exacerbations. It is ushered in rather acutely in some cases and there is marked destruction of the joints in a comparatively short period of time, while in others the disease is more or less quiescent for a period of years. I have seen some cases in which chronic atrophic arthritis has been present for thirty years with no resultant deformities in the joints. I have seen others in which the patient has been made a cripple in the relatively short space of six to eight months. Perhaps it is this protean nature of the disease that accounts for the different pathologic pictures. It is hoped that the photomicrographs shown in this article demonstrate most of the changes that occur in the synovial layer in atrophic arthritis. The picture varies from one in which there is polymorphonuclear infiltration (this section being obtained in a joint which was quite active at the time of operation) to

sections showing round cell infiltration, both perivascular and nonperivascular. A "burnt out" case showing the process after many years of involvement, with little round cell infiltration but replacement of the synovial tissue by means of scar tissue, is shown. It must also be remembered that atrophic arthritis is both a common and a chronic disease, and that, therefore, other diseases may be associated with this condition and may tend to give a varied pathologic picture. Conditions such as syphilis and hypertension, and other diseased conditions, which may affect the blood vessels of the body, must be remembered, since they must be ruled out before concluding that the pathologic picture found in the synovial tissue is the one that is characteristic of atrophic arthritis. It is hoped that correlated clinical and pathologic studies, even though they be a few cases, may offer much in the elucidation of the processes involved in atrophic arthritis.

SODIUM SULFAPYRIDINE MONOHYDRATE INTRAVENOUSLY IN THE TREATMENT OF LOBAR PNEUMONIA*

ABEL LEVITT, M.D., F.A.C.P., HAROLD T. SCHWEITZER, M.D., AND
KENNETH GOLDSTEIN, M.D., BUFFALO, N. Y.

CHEMOTHERAPY in the treatment of pneumonia has undergone considerable change in recent years. As a result of the introduction of sulfapyridine in the treatment of the disease, the mortality rate has markedly declined. In 1939 we reported the results of treatment of 100 consecutive cases of lobar pneumonia by oral administration of sulfapyridine. Our mortality rate in that group was 3 per cent. We observed no serious reactions to the drug, although there were some mild toxic manifestations. Occasionally the condition of the pneumonia patient is such that the oral use of this essential therapeutic agent is impossible because of nausea, vomiting, delirium, and other complications. Here the parenteral use of the drug becomes necessary. On the Medical Service of the Edward J. Meyer Memorial Hospital, sodium sulfapyridine monohydrate

*From the Medical Service of the Edward J. Meyer Memorial Hospital and the University of Buffalo School of Medicine.
Received for publication, December 14, 1940.

was used intravenously in 25 cases in order to compare its effect when thus given to the oral administration of sulfapyridine.

In this group of cases there were about an equal number of males and females, between the ages of 20 and 70 years, the majority of them being under 50 years of age.

Table I indicates the duration of illness prior to admission to the hospital when treatment was instituted.

TABLE I
DURATION OF ILLNESS PRIOR TO HOSPITALIZATION

NO. OF DAYS	NO. OF CASES	PER CENT
0-2	17	68
3-5	5	20
6-9	2	8
10-14	0	0
Above 2 weeks	1	4

It will be noted that about one-third of the cases did not enter the hospital until the third day or more after the onset of the disease.

Sputum typing and blood cultures were done on each case, and results are recorded in Table II.

TABLE II
LABORATORY STUDIES

TYPE OF PNEUMOCOCCUS	NO. OF CASES	BLOOD CULTURE	RESULTS
I	1	Positive	Recovered
II	6	Positive in 1 case	5 recovered 1 died
III	2	Negative	Recovered
IV	3	Positive in 1 case	Recovered
VIII	2	Negative	Recovered
Undetermined	2	Negative	Recovered
Negative	9	Negative	8 recovered 1 died

This year there appeared to be quite a diversity in the pneumococcic types of pneumonia. Usually we find a more predominant type, but the virulence in each particular type varies considerably from time to time. Blood counts were done in each case daily. The majority of our cases had a leucocytosis prior to the administration of the drug. In only rare instances did we use the drug when the white blood count was less than 10,000.

Table III shows the blood counts before treatment.

TABLE III
BLOOD COUNTS

METHOD OF ADMINISTRATION OF SODIUM SULFAPYRIDINE MONOHYDRATE

After the diagnosis of lobar pneumonia had been made and corroborated by x-ray, each patient was placed on a liquid diet containing a minimum of three liters per day, made up of fruit juices and milk. If oral fluids were not taken in sufficient quantity, we resorted to parenteral administration of saline and glucose. The only other routine therapeutic agent used was an opiate if indicated for cough or sedation, and in some instances oxygen by nasal catheter. The latter, however, did not seem to relieve the cyanosis when present while this drug was being used.

The sodium sulfapyridine was administered slowly intravenously, using a 5 per cent solution (4 Gm. of the powder dissolved in 80 c.c. of distilled water). Eighty cubic centimeters were given daily, and the blood was examined for per cent of sulfapyridine content at frequent intervals during the twenty-four hours. In rare instances the dose was repeated before the twenty-four hours were up in order to maintain a higher blood level. We did not supplement this therapy with the oral use of the drug, since we desired to determine its effect by the intravenous method only.

TABLE V
REACTIONS

REACTION	INTRAVENOUS 25 CASES (%)	ORAL 100 CASES (%)
Nausea and emesis	84	17
Cyanosis	52	18
Headache	36	None
Delirium	16	4
Jaundice	12	None

By this method of administration when a single dose was given daily, irrespective of size of the patient, the per cent of sulfapyridine in the blood shortly following injection (ten minutes) reached an average level of 8 mg. per cent and dropped about 20 per cent after an interval of one hour. Determinations at the end of four hours showed an additional 5 per cent drop. At the eighth hour there was an average decrease in sulfapyridine of 37.5 per cent. Recording of blood level for the drug at the end of twenty-four hours showed no appreciable change from the eight-hour level, the average being about 5 mg. per cent. Since it is advisable to maintain a blood level between 5 and 10 mg. per cent, it seems that the drug should be administered at least twice daily, and in some instances three times daily. With the above dosage the blood concentration, as noted in Table IV, varies considerably in each patient, irrespective of age, sex, or weight. When using sulfapyridine orally, the dose used was 2 Gm. on admission, followed by 1 Gm. every six hours and continued for three days following drop of temperature to normal. The blood concentration level on the average in twenty-four hours, with use of the oral drug, was 3.93 mg. per cent, while with the intravenous drug given once daily, it was about 5.6 mg. per cent. The duration of illness following the intravenous administration of the drug varied somewhat. In about 40 per cent of the cases the temperature came down by lysis or crisis within forty-eight hours. In one-third of the group this oc-

curred within four days. The remainder varied between five and eight days, none more than eight days. This compared closely with the data obtained with the oral use of the drug.

Reactions were similar to those obtained when sulfapyridine was used orally. Nausea and emesis were present in a large group of our cases with the intravenous use of the drug. Cyanosis was more marked, headache was present in a third of the group, jaundice (hemolytic) was observed in two cases (none in oral group), and a toxic hepatitis with regurgitant jaundice was noted in one case.

SUMMARY AND CONCLUSIONS

In this group of 25 cases we have had two deaths: one was a senile patient with hyperthyroidism who died from heart failure; the other had type II pneumonia and developed toxic hepatitis. Of significance in our group was a patient with an eight months' pregnancy who was delivered and recovered. Another had an infected abortion; she developed pneumonia and recovered. One had malignant hypertension and uremia, recovered from the pneumonia, but died some weeks later from his cardiovascular disease. We do not consider his death due to pneumonia.

The intravenous use of sodium sulfapyridine monohydrate has no particular advantage over the oral use of sulfapyridine or sulfathiazole when the latter can be taken orally by the patient. In those patients who for some reason are unable to take the drug orally, the intravenous sodium sulfapyridine should be used in conjunction with pneumonia sera when indicated. From experience, one to two injections daily of 80 c.c. of 5 per cent solution are required to maintain a blood concentration of 5 to 10 mg. per cent. If laboratory facilities are available, one could, by frequent blood examination, determine the exact frequency for the administration of the intravenous drug.

THE AVERAGE LENGTH OF LIFE OF THE RED CORPUSCLE*

DONA GAYLER GRAAM, A.M., PH.D., TERRE HAUTE, IND.

IN THIS study an attempt is made to add to the knowledge of the ever recurrent problem of the length of life of the red corpuscle. Hunter (1884 and 1887), and later Ashby (1919), have given a very good brief history of early investigations. Ashby (1919) also explains why, as yet, we cannot consider the problem solved. Escobar and Baldwin (1934) add somewhat to these early investigations.

Many chemists because they have perfected accurate methods for bile pigment estimation feel that they can thus determine the number of corpuscles destroyed every day and hence the number made every day if their number remains constant. Whipple (1926) criticizes this view by pointing out that there are at least two unknown factors which could seriously disturb these calculations. First, muscle hemoglobin certainly contributes to the amount of bile pigment. Second, hemoglobin set free in the circulation may be changed to bile pigment and urobilin, or it may be used again in hemoglobin construction. Miss Ashby (1919) (1921)^{1, 2} has done the most acceptable work so far on this subject. She has shown that the transfused corpuscles live in a recipient's blood stream for thirty days or more. The chief objections to accepting her results as far as the length of life of the corpuscles is concerned have been discussed by the others. Wean and Warren¹⁷ point out that what may be the length of life of a transfused corpuscle may not be the length of life of a native corpuscle. Foreign cells, especially of a different blood group, which necessarily were used by Miss Ashby, may not be as susceptible as native cells to ordinary means of destruction. A second objection is made by Rous (1923) that the "foreign" protein of the stroma of the transfused corpuscles may be utilized over and over again by the recipient and thus form corpuscles unlike the usual corpuscles of the recipient.

Eaton and Damren (1930)^{3, 6} explained a method for the estimation of the average length of life of the red corpuscle which has been verified only recently by kinsmen Moore and Harrison (1940). They considered the red blood corpuscles of the blood stream as a population. In a population that remains constant, as many individuals die as are born, or vice versa. If in that population a catastrophe occurs which destroys one-third or one-fourth of the population, immediately an increased number of blood corpuscles, all approximately the same age, is thrown into the blood stream. These new individuals

*From a private clinical laboratory, Rose Dispensary Building, Terre Haute, Ind.

A preliminary report was made in a manuscript submitted as partial fulfillment of the requirements for the degree of Doctor of Philosophy in the Department of Physiology of the Graduate School at Indiana University. This article represents much subsequent work.

Received for publication, December 18, 1940.

that restore the population are called reticulocytes and can be followed by using a special technique (Spohr, 1930). The new thing that Eaton and Damren (1930)^{7, 8} point out is the fact that in a population where there are so many individuals of the same age, these individuals finally arrive at that age, corresponding to their average age; then a greater than the usual number die at the same time. This intravascular hemorrhage is sufficient to stimulate another noticeable reticulocyte production. They claim that the average length of life of the corpuscle is the length of time between two successive peaks of reticulocyte production. The one objection to their conclusion is that the second peak of reticulocyte production would occur *at an appropriate distance after the death of a great number of corpuscles that had lived their average length of life and that had appeared in response to the initial hemorrhage.*

By making a daily total erythrocyte count along with the daily reticulocyte count, any unusual population of old corpuscles dying at one time will show itself in the drop in erythrocyte count. This "death drop" may amount to as much as a million per cubic millimeter of blood within a period of two days, as will be shown in the subsequent description of my experiments upon the rabbit. That this sudden death of erythrocytes represents the termination of the natural length of life of the reticulocytes born in response to the previous hemorrhage can scarcely be doubted.

Definition of Reticulocytes.—Any mammalian red corpuscle showing a stippling, tiny threads, or network light or heavy when stained with brilliant cresyl blue is called, in this paper, a reticulocyte. Key (1921) explains this basophilic substance in a rather complete manner. King (1928)¹² also gives a concise statement concerning the reticulocyte and Cunningham (1920) describes them rather well.

Experimental Procedure.—Well-nourished rabbits, as determined by weight and red blood count of between six and seven millions and a high hemoglobin percentage, and of known age were kept under uniform conditions in the laboratory. The food consisted of mixed ground grain in pellet form, alfalfa hay, and crushed oats with some green food every day.

A control period of several days was run in the case of each rabbit to determine the normal variation in the percentage of reticulocytes, red corpuscles per cubic millimeter of blood, and in one case the hemoglobin per cent. If an animal had more than 2.5 per cent, that animal was discarded. The drop of blood for the daily test was withdrawn from the marginal ear vein by the puncture method, at approximately the same time each day and before the animal was fed.

The blood for the hemorrhage was removed directly from the heart by means of a hypodermic needle and without the use of an anesthetic. An amount of blood estimated to be one-fourth to one-third of the total blood, or about 1.25 per cent of the body weight, was withdrawn. The blood was withdrawn slowly so that the vasomotor system could compensate for its loss. The animal was held quietly by the assistant for a period of five or ten minutes after the hemorrhage and then put back in his hutch and fed and watered as usual.

A period of forty-eight hours after hemorrhage was allowed to pass before the daily tests were begun again. Male rabbits only were used.

Staining Technique.—I am indebted to Dr. J. A. Badertscher for the method used in staining the reticulocytes of mammalian blood. The method is simple, quick, and accurate and has not been published.

A drop of fresh blood is placed directly on a glass microscope slide, taken from the ear of a rabbit or finger of a human being. A glass rod, on the end of which is deposited brilliant cresyl blue stain,* is used to stir the blood until it is colored a uniformly greenish blue. The edge of another microscope slide is then placed in the droplet of blue-colored blood. Sufficient time is allowed for the blood to flow along the edge of the touching surface of this latter slide. Then the blood on the edge of this latter or second glass slide is spread on to a third slide by pushing it along on the surface of the third slide in the usual way of making a blood smear. As many as eight or ten blood smears can be made on as many different glass slides from the one drop of stained blood, providing the edge of a clean slide is used every time for spreading the blood on other clean slides.

As soon as the blood smear is made and before it is dry, it should be held in a moist chamber a few seconds. The mouth is a very good moist chamber, providing the breath is held while the slide is in it. This permits the corpuscles to be exposed to a saturated stain longer than otherwise, and there is less distortion of the corpuscles. The moisture of the breath, if blown on the slide, will cause hemolysis of the corpuscles. The smear dries in a minute or two after it is removed from the moist chamber and is then ready to be counterstained with Wright's stain, mounted in balsam, and examined at any subsequent time.

Counting.—In the determination of reticulocyte percentage, the cells were counted by means of an ocular Micrometer Disc. The total red blood cell count and the reticulocyte cell count for successive squares were each determined. This was continued until a thousand or more cells had been counted and then the percentage of reticulocytes was estimated.

In making the red blood corpuscle count for the total number of red corpuscles per cubic millimeter of blood, Trenner diluting pipettes and Levy-Hausser counting chambers were used.

RESULTS

Young Rabbit.—Table I and Fig. 1 present the results of an experiment on a young rabbit of from six to seven months old. The experiment lasted twenty-nine days. The conditions of the blood were quite regular during the control period of six days. The average number of red blood corpuscles per cubic millimeter of blood remained constant near 6.4 million, and the hemoglobin estimate was 92 per cent. The reticulocyte percentage fluctuated only slightly, which fluctuation could reasonably be within experimental error. The reticulo-

*A saturated solution of brilliant cresyl blue, using 100 per cent alcohol as a solvent, is used. The tip of a glass rod is dipped in the solution, and the alcohol is burned off in the flame of an alcohol lamp. The glass rod is dipped three or four times until sufficient dye is deposited on the glass rod.

cyte percentage averaged 2.4 per cent, which would make the actual number of reticulocytes present at any one time, per cubic millimeter of blood, about 153,600.

On the sixth day of the experiment after the three blood tests mentioned above had been made, the animal was bled of an estimated one-fourth to one-third of its blood, or about 40 c.c. A period of forty-eight hours was allowed to elapse in order that the liquids of the body could adjust themselves, and then the blood was studied again daily until the end of the experiment. On the eighth day of the experiment, two days after the hemorrhage, a marked change due to prehemorrhagic conditions was shown in the blood when the red corpuscle count, reticulocyte percentage, and hemoglobin percentage were taken. The red corpuscle count had fallen to 4.1 million, the hemoglobin percentage to 56, and the percentage of reticulocytes had increased to 5.1.

Fig. 1.—The per cent of reticulocytes, the total red corpuscle count, and the hemoglobin percentage were taken before and after a hemorrhage of 40 c.c. of blood, approximately one-fourth of its blood. These were taken on the day of the hemorrhage and again after forty-eight hours. Three peaks of reticulocyte formation occurred on the 11th, 20th, and 28th days of the experiment. The total red corpuscle count was lowest on the 13th and 26th days of the experiment. The average length of life of the red corpuscles can be estimated by counting the days between the 11th and 18th days and between the 20th and 26th days. The average length of life of the red corpuscles was 6.5 days.

The increase in reticulocytes was actual as well as relative. Although the erythrocyte number per cubic millimeter was less than two-thirds the pre-hemorrhagic number, the actual number of reticulocytes per cubic millimeter was 209,100 instead of the 153,600 actually present at any one time in a cubic millimeter of blood during the control period. The expected drop in the number of erythrocytes, if one-third of the blood had been removed, would have been to 4.3 million, and the actual number was approximately 4.0 million. The per-

centage of reticulocytes gradually increased up to 9 per cent on the eleventh day of the experiment, and the whole cycle of reticulocyte formation lasted until the seventeenth day of the experiment. The actual number of reticulocytes present per cubic millimeter of blood at the peak of their production was 450,000 as compared to the 153,600 during the control period. The per cent of hemoglobin and the total number of erythrocytes reached normal levels nine days, sometimes ten, after hemorrhage on the one hundred and forty-fifth or fifteenth day of the experiment, and fluctuated near that level, steadily working upward, however, until the end of the experiment.

The rate of reticulocyte production remained higher than during the control period until the number of erythrocytes and the per cent of hemoglobin were almost normal on the fourteenth or fifteenth day of the experiment. On the sixteenth day the erythrocyte number was actually above the control period. The reticulocyte curve continued to fall for two or three more days, fifteenth to seventeenth day. On the eighteenth and nineteenth days there was a rather sudden drop, which amounted to almost a million per cubic millimeter of blood in the number of erythrocytes. The hemoglobin curve followed the erythrocyte

curve, more or less, except that there seemed to be a slight tendency for the hemoglobin curve to lag behind the erythrocyte curve toward the end of the experiment.

The rapid fall in number of erythrocytes on the seventeenth and eighteenth days was equal to a hemorrhage and can well be called an intravascular hemorrhage. It was sufficiently severe to stimulate another wave of reticulocyte production. This peak of reticulocyte production was on the twentieth day. As a result, the erythrocyte number returned to normal and even went quite above normal, reaching a new peak on the twenty-fourth and twenty-fifth days. At the same time the reticulocytes fell below the normal production. The third slight peak of reticulocyte production on the twenty-eighth day can scarcely be regarded as a response to the drop in erythrocytes on the twenty-sixth day, since the total does not go below normal. Because the total red corpuscle count ran above normal, the per cent of reticulocytes was below normal.

25	10/30	---	Died	---	---

The period of time between the greatest production of reticulocytes on the eleventh day and the fall in the number of erythrocytes about the eighteenth day must be regarded as the average length of life of the red corpuscle. This period is approximately seven days. It is also quite possible that the time between the second peak of reticulocyte production at the nineteenth or twentieth days, and the fall in erythrocyte number on the twenty-sixth day, would represent the same thing. Here, too, the time is approximately seven days.

Old Rabbit.—An experiment similar to the above was performed on an old rabbit (5½ to 6 years), the details of which are presented in Fig. 2. The experiment covered a period of twenty-four days, at which time the animal died. This rabbit, although old, was in good condition until on or near the twenty-first day, three days before death, the rabbit showed signs of weakness and diarrhea, probably due to too large an amount of green food during the weakened period subsequent to hemorrhage. The reticulocytes stained more deeply at this time, and can be considered polychromatophiles. The important part of the experiment was completed before these symptoms appeared.

Fig. 2.—The per cent of reticulocytes and the total red corpuscle estimate were taken before and after a hemorrhage of 40 c.c. of blood, approximately one-fourth of its blood. These were taken on the day before the day of the hemorrhage and again after seventy-two hours. Two days after the hemorrhage two peaks of reticulocyte formation occurred on the 13th and 20th days of the experiment. The total red corpuscle count was lowest on the 18th day of the experiment. The average length of life of the red corpuscles can be estimated by counting the days between the 13th day and the 18th day. The average length of life of the red corpuscles was 5 days.

The hemoglobin was not tested in this experiment, since it was not deemed necessary. The control period lasted nine days. The average number of erythrocytes was six million, and the percentage of reticulocytes was 1.6 per cent. Tests were not made on the day of the hemorrhage, but they were made forty-eight hours later as well as on every subsequent day thereafter. On the twelfth day of the experiment, forty-eight hours after hemorrhage, there was a drop in erythrocytes to 4.5 millions and a rise in reticulocytes both in percentage and in actual number per cubic millimeter of blood.

The greatest percentage of reticulocytes occurred on the thirteenth day and the greatest destruction of erythrocytes occurred on the eighteenth day. The length of time between the peak of reticulocytes and the fall in the total number

Fig. 3.—The per cent of reticulocytes and the total red corpuscle estimate were taken before and after a hemorrhage of approximately one-fourth of its blood. These were taken on the day of the hemorrhage and again after forty-eight hours. Two peaks of reticulocyte formation occurred on the 10th and 16th days of the experiment. The total red corpuscle count was lowest on the 15th and 22nd days of the experiment. The average length of life of the red corpuscles can be estimated by counting the days between the 10th and the 15th days and between the 16th and 22nd days, respectively. The average length of life of the red corpuscles was estimated as 5.5 days.

Fig. 4.—The per cent of reticulocytes and the total red corpuscle estimate were taken before and after a hemorrhage of approximately one-fourth of its blood. These were taken on the day of the hemorrhage and again after forty-eight hours. Two peaks of reticulocyte formation occurred on the 14th and 26th days of the experiment. The total red corpuscle count was lowest on the 19th or 20th and on the 26th or 27th days of the experiment. The average length of life of the red corpuscles can be estimated by counting the days between the 14th and 19th or 20th days and between the 26th and 27th days. The average length of life of the red corpuscles was estimated as 5.5 days.

of corpuscles per cubic millimeter of blood was five days. This five-day period must be considered the average length of life of the red corpuscles of an old rabbit.

It will be noticed that the number of erythrocytes never returned to the normal level after hemorrhage.

Middle-Aged Rabbits.—The tables showing data for these two rabbits were omitted to save space, but the data of these tables were used in constructing the two graphs, Figs. 3 and 4, as well as Table III, where a comparison of all four rabbits was made. The average length of life of the corpuscles of each of these two rabbits was five to six days.

TABLE III

COMPARATIVE STUDY OF TOTAL BLOOD COUNT AND RETICULOCYTE PERCENTAGE OF FOUR RABBITS OF DIFFERENT AGES

RABBIT	R.B.C. PER CU. MM. OF BLOOD (CONTROL PERIOD)	RETICULOCYTE PERCENTAGE (CONTROL PERIOD)	AVERAGE LENGTH OF LIFE OF R.B.C.	R.B.C. MADE EACH DAY PER CU. MM. OF BLOOD	NO. OF RETICULOCYTES ACTUALLY PRESENT AT ANY ONE TIME PER CU. MM. OF BLOOD (CONTROL)	DURATION OF RETICULOCYTE STAGE
Young rabbit No. 1 Aged 6-7 mo.	6,400,000	2.4	6-7 days Avg. 6.5 days	981,615	153,600	3 hr. 45 min.
Middle-aged rabbit No. 3 Aged slightly less than 2 yr. (approx.)	6,850,000	2.39	5-6 days Avg. 5.5 days	1,245,454	163,715	3 hr. 10 min.
Middle-aged rabbit No. 4 Aged 2 yr. (approx.)	5,880,000	2.63	5-6 days Avg. 5.5 days	1,069,000	137,000	3 hr. 4 min.
Old rabbit No. 2 Aged 5½-6 yr.	6,000,000	1.6	5 days	1,200,000	96,000	1 hr. 55 min.

DISCUSSION—COMPARISON

The blood pictures of the young rabbit, Fig. 1, and the old rabbit, Fig. 2, were very similar during their respective control periods. The erythrocyte count of the young animal averaged 6.4 million, and the count of the old animal averaged 6 million. The reticulocyte percentage of the young rabbit averaged 2.4 and that of the old rabbit was 1.6. An amount of blood calculated to be approximately one-fourth to one-third of the total blood volume was removed from each animal at the end of the control period. Forty-eight hours were allowed to elapse before the daily tests were begun again.

The initial reticulocyte response of the young rabbit was greater and lasted over a longer period of time than that of the old rabbit, while the second peak of reticulocytes was higher in the old rabbit than in the young one. The time between the reticulocyte peaks for the young and old rabbits was nine and seven days, respectively. The explanation of this difference may be that the young rabbit produces enough reticulocytes during the first response to

bring the number of erythrocytes back to normal level, while the hemopoietic response in the case of the old animal was never sufficient to restore the original number of erythrocytes. Furthermore, more erythrocytes died at one time in the old animal and precipitated a higher second reticulocyte peak proportionately than in the case of the young animal.

On the ninth day after hemorrhage the young rabbit had its erythrocytes restored to a low normal, while, on the other hand, the old rabbit never returned to normal; in fact, it scarcely gained in number of erythrocytes at all.

Although the reticulocyte production was not complete enough and the cycle was not long enough before the subsequent intravascular hemorrhage occurred, due to a short length of life of the corpuscles, the conclusion reached was that the animal's red corpuscles decreased in number with each subsequent intravascular hemorrhage.

Seven days after the peak of reticulocytes in the young rabbit, there was a fall in total number of erythrocytes of approximately a million. In like manner five days after the peak of reticulocytes in the old rabbit, there was a fall in the total number of reticulocytes of a million or more. It cannot be doubted that the fall of a million in total number of erythrocytes in both animals on the eighteenth day of each experiment was due to an intravascular hemorrhage, a loss of erythrocytes born at the previous peak of reticulocyte formation. A second peak of reticulocytes, followed by an intravascular hemorrhage, was shown in the young rabbit. The period was between the nineteenth or twentieth days and the twenty-sixth day of the experiment.

Since the period of seven days in the young animal and the period of five days in the old animal must represent the average length of life of the red corpuscles in the two animals, the conclusion would be that the erythrocyte lives longer in the blood stream of a young animal than it does in the blood stream of an old one. This conclusion is further borne out in the results from two middle-aged (2 years old) rabbits in which the average length of life of the corpuscles was 5.5 days (see Table III).

The time between the hemorrhage and the first peak of reticulocyte response, five days and four days, respectively, in the young and old rabbits, was greater than the time between the intravascular hemorrhage and the succeeding reticulocyte response, two days each in young and old. The explanation, no doubt, is that the intravascular hemorrhage did not involve loss of volume; therefore, the time should be correspondingly decreased. Robertson and Boch (1919)^{14, 15} have shown that it is the reduced hemoglobin per unit of blood due to dilution of the blood after hemorrhage that is the stimulating factor in reticulocyte formation.

Knowing the total number of erythrocytes per cubic millimeter of blood and the percentage of reticulocytes, the actual number of reticulocytes per cubic millimeter of blood can be determined: $6,000,000 \times 1.6$ per cent = 96,000 reticulocytes (see Table III, old rabbit).

Knowing the length of life of the red corpuscles, the number of corpuscles made each day may be determined: $6,000,000 \div 5 = 1,200,000$ (see Table III, old rabbit).

Knowing the foregoing, the reticulocyte period can be determined: $1,200,000 \div 96,000 = 1/12.5$ of a day, or one hour and fifty-five minutes (see Table III, old rabbit).

By similar calculation the reticulocyte stage in a young animal was found to last three hours and forty-five minutes. The comparative data are set out in Table III.

Calculations made for the two other rabbits shown in Table III are also tabulated. In practically every respect the blood pictures of the two, 2-year-old rabbits show conditions midway between the young and old rabbits.

The ability of the rabbit to recover from hemorrhage is due to a combination of the length of life of the corpuscle and of the number of corpuscles thrust into the blood stream in twenty-four hours. In the case of the young rabbit No. 1 the recovery was rapid because the length of life of the corpuscle is long and the number of reticulocyte percentage is high. The old rabbit No. 2 showed the other extreme, the reticulocyte percentage being low and the average length of life of the corpuscle short. It was unable to recover. Rabbits Nos. 3 and 4 recovered easily because the reticulocyte percentage was high, although the length of life of the corpuscles was somewhat shorter than in the case of rabbit No. 1.

Furthermore, the actual number of reticulocytes produced per cubic millimeter of blood every twenty-four hours was actually greater during the control period than that of the young rabbit; e.g., the young rabbit produced 984,615 reticulocytes per cubic millimeter of blood as compared to 1,200,000 produced by the old rabbit per cubic millimeter of blood.

CONCLUSIONS AND SUMMARY

1. After hemorrhage the reticulocyte cycles follow one another at regular intervals of a few days. The second reticulocyte cycle and each succeeding one is preceded by an intravascular hemorrhage in which corpuscles are destroyed but the volume of blood remains constant.

2. The longest period noted between reticulocyte cycles was nine days in a young rabbit, and the shortest period was seven days in an old rabbit.

3. The average length of life of the red corpuscle is equal to the period between the peak of a reticulocyte cycle and the end of the succeeding intravascular hemorrhage.

4. The average length of life of the red corpuscle of a rabbit varies inversely with age—the younger the rabbit, the longer the corpuscles live.

5. The average length of life of the red corpuscle varies from six to seven days in a young rabbit to five days in an old rabbit.

6. The extreme length of life of a red corpuscle may be much longer than the average life because many may be destroyed in "infancy" or in "early adult life."

7. The number of red corpuscles liberated into the blood stream each twenty-four hours by a young rabbit was 984,615 per cubic millimeter of blood, and by an old rabbit, 1,200,000 per cubic millimeter of blood.

8. The number of reticulocytes present per cubic millimeter of blood was 153,600 for a young rabbit, 96,000 for an old rabbit, and 1,245,451 and 1,069,000 for two middle-aged rabbits.

9. The duration of the reticulocyte stage was approximately four hours in a young rabbit and two hours in an old rabbit. The reticulocyte stage in the two other rabbits, aged 2 years, was about midway between that of the old and young animals; namely, 3 hours 10 minutes, and 3 hours 4 minutes, respectively.

10. An accurate picture of the activity of the red bone marrow can be obtained if the number of red corpuscles per cubic millimeter of blood, the average length of life of the red corpuscles, the per cent of reticulocytes present in the blood, and the duration of the reticulocyte stage of the red corpuscle are known.

I take this opportunity to thank Dr. William Moenkhaus and Dr. Paul Harmon, of the Physiology Department of Indiana Medical School, for help and encouragement.

THE EFFECT OF LOWERED TEMPERATURES UPON THE GROWTH OF THE FIBROBLAST IN VITRO: ITS APPLICATION TO WOUND HEALING*

MACHTELD E. SANO, M.D., AND LAWRENCE W. SMITH, M.D.,
PHILADELPHIA, PA.

IN THE course of tissue culture studies relating to the growth of embryonal and cancer cells under the influence of varying temperatures,† the behavior of the fibroblast has been so outstanding that it merits separate consideration. The vital importance of the role of this cell in wound healing and repair processes in general makes our understanding of its unusual resistance to cold and its adaptability to unfavorable environmental circumstances of especial significance.

At body temperature (37° C.) and under ideal culture conditions, in respect to material and media, the fibroblast multiplies rapidly and produces large, elongated, healthy appearing cells, with obvious coarse fibroglia fibers. It is not necessary to go into great detail regarding this aspect of the problem, as the behavior of the fibroblast under such circumstances has been thoroughly investigated by many competent observers.^{3, 5-7, 10} Like these other investigators we have found that the rate of such normal growth is not maintained for any considerable period in vitro unless the cultures are transplanted at frequent intervals. Otherwise the cells revert to what might be termed a "resting" or resistant phase, not unlike the encystment stage of certain parasites, only to grow again at a normal rate after a brief lag period when transferred to fresh media.

The resistance to lowered temperatures of the fibroblast is very marked. Initial congelation at 0° C. for as long as sixty hours does not significantly alter the growth capacity of these cells when the cultures are subsequently placed in the incubator at 37° C., other than for the usual lag noted previously in the tumor cell cultures. Nor is any inherent difference in the growth noted in parallel cultures with the temperature lowered gradually from an initial 37° C., as compared with those started off at the corresponding lower levels.

At 30° C. obvious differences in the appearance of the fibroblasts from those grown at 37° C. are seen. The cells are smaller both in respect to the size of the nucleus and the amount of cytoplasm. This decrease in size is especially prominent in respect to the length of the cell, the whole cell appearing more compact and sturdy, with ovoid rather than spindle nuclei.

†In press. Cancer Research, January, 1942.

At 25° to 26° C. the fibroblasts are scarcely a third the size of those grown at 37° C. and show only little intercellular substance. Instead of migrating freely and extending in long fingerlike projections from the mother colony, they are arranged in almost solid radiating phalanx fashion, several cells deep, around the original explant. The cytoplasmic and nuclear detail is well defined in both unstained and vitally stained specimens.

Fig. 1.—Normal mouse lymph node at 37° C. Approximate magnification, $\times 150$.

At 20° C. the rate of growth is still further retarded. Six or seven days elapse before the first evidence of new cell formation can be made out. At this temperature level the cells are likewise still further diminished in size, scarcely a fifth that of those grown at 37° C. They are very short and stubby in appearance, almost round or polyhedral rather than ovoid or spindled. As they slowly increase in numbers they occur in small sheets at the edge of the original inoculum, but it takes several weeks for this to occur.

At the 24° to 26° C. temperature levels the cells are far more resistant to environmental factors. This may be accounted for in several ways. Owing to their more compact arrangement they are less readily damaged physically by washing and changing their media. Owing to their slower rate of growth they survive in the original medium for a much longer period of time than the larger more rapidly growing fibroblasts at 37° C. This is undoubtedly due in part to their lower nutritional requirements, but also to the reduction in the metabolism of the cells, with a corresponding reduction in the concentration of the products of metabolism in the medium. This latter feature has been stressed by many writers, as well as ourselves in other communications, as being one of the very important factors which interfere with tumor cell culture. As part of this slowed metabolism the usual regressive degenerative changes of the cytoplasm of cells grown "in vitro" are obviously retarded, which in turn fits in with the previous comments in helping to explain the increased resistance of these cells to lowered temperatures.

We believe that these observations are well established and might be expressed almost mathematically because of their constancy in the case of literally

hundreds of such tissue explants. There is a direct proportional relationship not only between the temperature and the rate of cell growth, but also in respect to temperature and the size of the cell, its degree of differentiation, its metabolic activity, and its resistance to environmental circumstance. On the basis of these studies a temperature range of 25° to 30° C. would seem to be optimal in respect to wound healing. Under such circumstances one logically might expect that the healing process would be somewhat slower than at body temperature, but that the amount of collagen production, with its subsequent ugly contraction and scar formation, would be reduced appreciably.

That this optimal reaction actually does occur clinically was shown by Smith and Fay¹² incidentally in their early studies concerning the effect of hypothermy on cancer cell growth. In one case, especially, of extensive ulcerative breast carcinoma treated by continuous local hypothermy for nearly six months, not only did the tumor disappear, but the ulcerated surface healed over completely with soft scar tissue having the consistency of normal skin. Histologic study of biopsy material from this and numerous other cases confirmed the clinical impression. The tissues showed a connective tissue relatively rich in nuclei and with a minimum of dense collagen formation.

Fig. 2.—Normal mouse lymph node at 30° C. Approximate magnification, $\times 150$.

The recent work of Allen¹ and his associates in the healing of diabetic and traumatic amputation stumps under the influence of cold is another illustration of the clinical application of this principle. In almost every instance healing by first intention resulted, and with a minimum of scar production. The repair process, as might be expected, was quite regularly delayed, requiring three to four weeks instead of the usual ten days to two weeks. On the other hand, the wounds did not break down, and the stumps presented a much more satisfactory end result for subsequent artificial limb appliances. As part of the mechanism involved in the use of hypothermy for such wound repair, it should be noted that the external temperatures employed (5° to 10° C.) are bacteriostatic, and thus the danger of secondary infection is almost eliminated. It should be further mentioned that actual freezing must be avoided, and that the penetra-

tion of the cold into the deeper tissues from local external application drops off with almost algebraic progression, so that the desired levels of 20° to 25° C. are actually present in the deeper tissues of the wound where the connective tissue repair process is going on.

On the basis of such clinical observations and the confirmatory laboratory evidence of the behavior of the fibroblast at these lower temperatures, the more widespread use of hypothermy in wound healing would seem to be warranted. Its application in plastic surgery, of the cosmetic type particularly, comes to mind immediately. The possible prevention of keloid formation is another field which might profitably be explored. Its place in clearing up old osteomyelitis lesions might likewise be investigated.

Fig. 3.—Schematic representation of fibroblastic proliferation at A, 37° C. and B, 30° C. Note the smaller size, compactness, and diminished intercellular products at the lower temperature.

It is of interest that these various tissue culture studies and clinical observations of ours are indirectly confirmatory of the fundamental work of Burrows⁴ on wound healing, although the approach to the problem is from a wholly different angle. Burrows noted that the growth of the fibroblast in his experimental wounds at body temperature was most profuse in the central areas which were less well vascularized than in the periphery of the lesion. He advanced the hypothesis that the fibroblasts grow better when they are closely packed together so that certain metabolic products of oxidation accumulate in optimal amounts, through their inability to be absorbed and carried away by an inadequate blood supply. By corollary he comments that if the wound is washed too frequently, the rate of growth of the fibroblasts is likewise reduced, and healing is thereby delayed and less satisfactory.

In our own studies the reduction of temperature to 25° or 30° C. gives us similar optimal conditions for satisfactory wound healing. The cells are growing vigorously; they are closely packed and the circulation is slowed. Thus the products of metabolism are in close contact with the cells, and remain so, through the inability of the slowed blood stream to carry them away. In addition these temperatures are bacteriostatic to a very considerable degree and aid materially in checking any infection which might be present (Fig. 3).

Finally, there is a definite relationship between epithelialization and fibroblastic proliferation in a wound. When the surface becomes covered with epithelium, the stimulus to fibroblastic proliferation is lost. If this epithelialization is accomplished too rapidly, the underlying granulation tissue tends to undergo regressive changes, the collagen contracts, and we have a depressed secondarily

contracted scar. If, on the other hand, the repair process is slower, the connective tissue is adequate in amount, compactly arranged, with relatively little collagen, and the final scar is minimal with little or no retraction. From our observations all of these prerequisites for good wound healing seem to be realized by temperatures between 25° and 30° C.

SUMMARY

The behavior of the fibroblast in tissue culture at varying temperatures ranging from 0° to 37° C. is recorded. An optimal level of around 25° C. is suggested as of practical value in wound healing.

Clinical observations of the use of hypothermy in various fields, including a review of some of the more recent literature, are presented.

A plea for the wider use of local hypothermy in various clinical problems relating to wound healing is made.

AN UNUSUAL P-WAVE IN CHEST LEAD CF₂ FOLLOWING SPONTANEOUS PNEUMOTHORAX*

S. D. BURTON, M.D., AND J. S. MEHLMAN, M.D.
CHICAGO, ILL.

ALTHOUGH it is well recognized now that changes in the position of the heart will alter the electrocardiogram, little work has been done to illustrate these changes in the chest leads. Recently we have had the occasion to follow the changes in the electrocardiogram caused by a spontaneous pneumothorax which occurred in a patient who had an abnormal electrocardiogram due to congenital heart disease. The electrocardiographic changes were correlated with changes in position of the heart as the pneumothorax appeared and then resolved. A control record was available before the pneumothorax developed, and serial electrocardiograms were taken during the course of the patient's illness.

A striking alteration in the P-wave of chest Lead CF₂ was especially noted. The changes in this P-wave were similar to, but more marked, than those reported by Gertz¹ from this department. This record serves to emphasize again that such P-wave changes are suggestive of a position change of the heart.

CASE REPORT

The patient was a 19-year-old white male, who entered Michael Reese Hospital on the service of Dr. W. A. Brams on Nov. 12, 1939, complaining of cough and pain in the chest of one day's duration. He was known to have had heart disease since birth, and his activities had always been restricted. He had been followed in the out-patient clinic.

On the morning of admission he was awakened by pain in his right chest and a nonproductive cough. On two occasions following a paroxysm of coughing, he became dyspneic and perspired profusely. There was no precordial pain or hemoptysis.

His past medical history revealed the presence of cyanosis since birth, pneumonia at the age of 5, measles, and chickenpox. One brother had rheumatic heart disease. Three other siblings, his mother and father, were all alive and well. He had had a series of electrocardiograms taken before this episode, one of which is shown in Fig. 1A.

On admission he had a temperature of 99° F., a pulse rate of 120, and a respiratory rate of 28 per minute. The blood pressure was systolic 96 and

*From the Cardiovascular Department and the Department of Medicine, Michael Reese Hospital, Chicago.

†Aided by the A. D. Nast Fund for Cardiac Research.

Received for publication, December 23, 1940.

diastolic 70. The patient was underdeveloped and thin. His skin was cyanotic. He was slightly dyspneic even with the back rest elevated at a 60 degree angle. There were no petechiae visible. The right hemithorax appeared larger than the left, and it moved less with respiration. Tactile fremitus was diminished, and the percussion note was hyperresonant over the entire right side of the chest. Breath sounds were absent, except for a small area of bronchial breathing beneath the clavicle. The pulmonary findings on the left side were normal. The apex beat was diffusely palpable in the fourth, fifth, and sixth left intercostal spaces as far laterally as the anterior axillary line. There was no cardiac dullness to the right of the sternum. The heart rhythm was regular, and the tones were loud. There was an accentuation of the first sound at the apex. No murmurs were audible at the time of this examination. The abdomen was negative. There was a moderate left thoracic kyphoscoliosis. Clubbing of the fingers and toes was marked. The diagnosis was congenital heart disease and right spontaneous pneumothorax.

An electrocardiogram was taken at this time (Fig. 1B). A teleoroentgenogram also taken on the day of admission showed a right pneumothorax with almost complete collapse of the upper and middle lobes against the mediastinum. The right lower lobe appeared 80 to 90 per cent collapsed. There was a slight upper dorsal scoliosis so that it was difficult to determine whether there was a shift of the heart or mediastinum to the left.

On Nov. 13, 1939, the venous pressure was 6.8 cm. of water, the circulation time (arm to tongue) by the calcium gluconate method was 15.5 seconds, and the vital capacity was 1,300 c.c. The intrapleural pressure on the right side varied between 0 and +4.0 cm. of water on quiet respiration. After 1,000 c.c. of air were aspirated from the right chest, the foregoing determinations were repeated. The vital capacity rose to 1,600 c.c., and the intrapleural pressure varied from -6.0 cm. to 0 cm. of water during respiration. Electrocardiograms were taken before and after aspiration of the air and are shown in Fig. 2, A and B. After aspiration Lead CF₂ was recorded with the patient in three different positions: (1) sitting up, (2) left lateral, and (3) right lateral (Fig. 3).

A chest film twelve hours after the aspiration of the air showed little change in the findings. Blood studies revealed an intense secondary polycythemia with a red blood cell count of 6,720,000, hemoglobin, 24.0 Gm. per 100 c.c. of blood, volume index of 1.1, color index 1.05 and a hematocrit of 71 per cent. Fluoroscopic examination on November 18 showed a persistence of the pneumothorax, with an almost total collapse of all three lobes of the right lung. The heart was slightly deviated to the left, with a rounded contour of its left border. The right ventricle was moderately enlarged in the right oblique. There was no left auricular or ventricular enlargement. The aortic knob was hardly visible.

The patient's course in the hospital was uneventful. Fluoroscopy on November 25, thirteen days after admission, showed 60 to 70 per cent collapse of the right lung still present. Another electrocardiogram was taken at this time (Fig. 1C). On December 4, twenty-two days after admission, 50 per cent collapse was observed on fluoroscopic examination. One week later almost all

physical signs of pneumothorax had disappeared. A loud systolic murmur at the apex transmitted toward the base was now audible. The remainder of the physical findings were unchanged. The possibility of a patent interventricular septum, moderate overriding of the aorta to the right ventricle, and narrowing of the infundibulum of the pulmonary artery were considered as the anatomic defects.

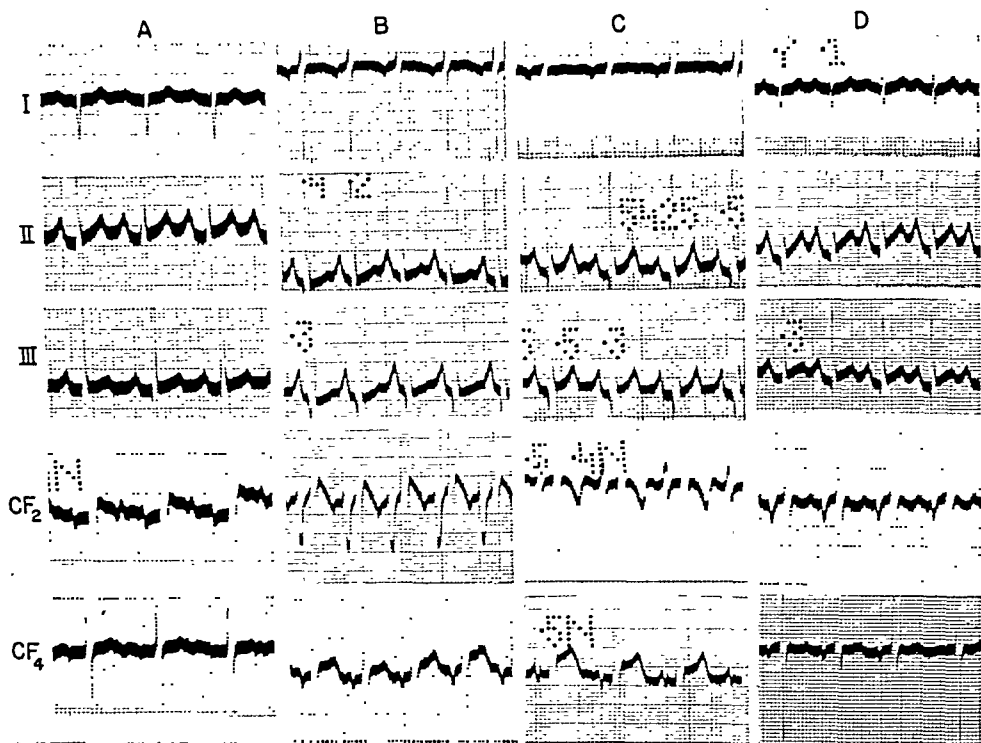

Fig. 1.—Effect of pneumothorax and its spontaneous resolution on the electrocardiogram. Segment A, control record taken on Jan. 9, 1939. Segment B, record taken on Nov. 13, 1939, after a spontaneous right pneumothorax. (Note the deeply inverted P-wave in Lead CF_2 .) Segment C, record taken on Nov. 25, 1939, when the right lung was 60 to 70 per cent collapsed. Segment D, record taken on April 6, 1940, when all evidence of the pneumothorax had disappeared. See text for discussion.

The patient was discharged on December 12, thirty days after admission, much improved. Further observations were made in the out-patient department. A teleoroentgenogram was taken on Feb. 3, 1940, and showed no evidence of a pneumothorax. A final electrocardiogram was taken on April 6, 1940 (Fig. 1D). His course since discharge has been essentially similar to that before the pneumothorax.

DISCUSSION

Examination of Fig. 1 shows the effect of the pneumothorax upon the electrocardiogram. Record A, the control, is abnormal, showing a right ventricular preponderance and peaked P-waves in the limb leads. Following the pneumothorax (segment B), marked changes in the S-T segment and T-wave were produced, and there was an increase in the axis deviation to the right. The most striking changes occurred, however, in the P-waves, and especially the

P-wave in Lead CF_2 ; this deflection consisted of a deeply inverted wave 14 mm. in amplitude, preceded by a tiny preliminary upright phase. With partial resolution of the pneumothorax, segment C, the electrocardiogram tended to revert toward its previous appearance and P-wave changes occurred in all leads. The P-wave in CF_2 was still large, but it had become diphasic with the first phase up. The record, segment D, taken after all evidence of the pneumothorax had disappeared is fairly similar to the control record taken before the

Fig. 2.—Effect of partial release of pneumothorax on the electrocardiogram. Segment A, control record (compare with segment B, Fig. 1). Segment B, record taken immediately after 1,000 c.c. of air had been withdrawn from the right pleural cavity. Note the decrease in the right axis deviation and the marked change in the P-wave in Lead CF_2 .

pneumothorax developed. It is, therefore, proper to ascribe the electrocardiographic alterations in this case to the pneumothorax. This statement is further supported by comparing the similarity in the changes which occurred immediately following the withdrawal of 1,000 c.c. of air from the chest (Fig. 2) and the more gradual changes illustrated in Fig. 1 (B, C, and D) as the process resolved spontaneously.

The P-wave in Lead CF_2 in these figures, although larger in amplitude, is similar to the one described by Gertz.¹ It is the type of deflection obtained by

Wilson, Macleod, and Barker² and others when a unipolar lead with one electrode connected directly to the auricle is applied. However, the phase relations of the P-wave in this case and in that of the authors just mentioned are mirror images because the lead connections to the galvanometer were reversed.

Fig. 3.—Records showing effect of postural changes in the electrocardiographic contour of the chest Lead CF_2 in this patient when the pneumothorax was present. Segment A, patient sitting upright. Segment B, patient in the left lateral recumbent position. Segment C, patient in the right lateral recumbent position. (Note the marked P-wave changes and the variations of the P-wave with respiration in segment C.)

The P-wave changes in this case must be ascribed to a displacement of the heart, such that the auricle comes to lie beneath the chest electrode. When the pneumothorax was at a maximum, viz., in Fig. 1B and Fig. 2A, the appearance of the P-wave suggests that the part of the auricle in which the pacemaker of the heart is located was lying close to the chest electrode. Such records, or rather their inverted images, because of the reversed electrode connections, have been obtained with unipolar leads in the neighborhood of the sinus node. In order for these P-wave changes to occur, it must be presupposed that the heart is pushed over laterally, ventrally, and caudally, and that it is also rotated in a counterclockwise direction when viewed from above. Counterclockwise rotation causes a deviation of the electrical axis to the right (Katz and Robinow³); this was observed in our case.

With resorption of the pneumothorax, the displacement of the heart was less marked. Hence the region of the sinus node became farther removed from the chest electrode, and at this stage a P-wave with more nearly equal phases was recorded (Figs. 1C and 2B).

As might be expected, the heart in a chest with a partial pneumothorax is more mobile than normal. This is shown by the changes in the contour of the electrocardiogram in Fig. 3 when the body posture was altered. In addition,

the respiratory variation in the P-wave contour was greatest when the patient was in the right lateral position with his heart supported from below by the collapsed lung and the pneumothorax (Fig. 3C). These shifts in the heart's position alter the relation of the heart to the good and poor electrical conductors in contact with its surface and lead to the variations in the electrical field. It has been shown that the conductors surrounding the heart vary in their ability to conduct the electric currents generated by the heart and that alterations in these contacts affect the electrocardiogram (Katz and Korey;⁴ Lindner and Katz⁵).

The view presented by Gertz¹ is thus confirmed and amplified: namely, that peculiar large P-waves in the chest Lead CF₂ may be a sign of cardiac displacement in which the right auricle is brought into close proximity with the chest electrode.

SUMMARY

A case is presented showing an unusual and deeply inverted P-wave of 14 mm. in Lead CF₂. This P-wave was produced by cardiac displacement, resulting from a spontaneous pneumothorax which brought the right auricle into close apposition to the anterior chest wall. The contour of the P-wave was such as to suggest that the part of the auricle beneath the chest contained the pacemaker, the sinus node. As the pneumothorax was relieved, the large P-wave became diphasic, suggesting the apposition of other parts of the auricle to the anterior chest wall. Finally, as further resolution of the pneumothorax progressed, the P-wave returned to its smaller and more nearly normal appearance, which existed before the pneumothorax occurred. During the period of pneumothorax, the changes in the P-wave with change in body posture indicated greater than normal mobility of the heart.

We are grateful to Dr. L. N. Katz, at whose suggestion this study was undertaken, for his advice and guidance.

CLINICAL CHEMISTRY

PLASMA ALBUMIN, GLOBULIN, AND FIBRINOGEN IN HEALTHY INDIVIDUALS FROM BIRTH TO ADULTHOOD*

II. "NORMAL" VALUES

VIRGINIA TREVORROW, PH.D., MARGARET KASER, PH.D., JEAN PATON PATTERSON, M.S., AND ROBERT M. HILL, PH.D.
DENVER, COLO.

THE literature records several studies of the plasma proteins in "normal" individuals. These values are not wholly adequate, since most of the studies have been made upon small groups of persons, chiefly adults, whose state of health in many cases is open to question. There is a great paucity of data with respect to plasma protein values in infancy and early childhood. In addition to this lack of adequate material, the existing studies have been based upon different methods of analysis which do not give comparable results. The many and varied functions attributed to the different protein fractions of the blood plasma have made it increasingly important that a quantitative study be undertaken to determine the amount of albumin, globulin, and fibrinogen present in the blood of healthy individuals. Such a study also furnishes the necessary foundation for the interpretation of findings in pathologic conditions. We have determined the concentration of the protein fractions in the plasma of 547 healthy persons by means of a salting-out separation of the different proteins, followed by Kjeldahl analysis. The details of our analytical procedure have been given in a previous publication.¹

MATERIAL USED

The subjects for this study were obtained from various sources. A few of the children were personal friends of ours, or children of the Child Research Council. The majority of the babies and younger children were from maternity hospitals or Homes at which they received regular medical supervision and in which the dietary was considered to be adequate. The adolescents were students at West Denver High School and were examined and questioned by a physician and one of us when the blood was taken. The adults were medical students and laboratory workers. In every case an attempt was made to rule out those who might present a clinical or subclinical variation in any of the protein fractions as a result of recent immunization, malnutrition, dehydration,

*From the Child Research Council and the Department of Biochemistry, University of Colorado School of Medicine, Denver.

Received for publication, October 20, 1941.

chronic or acute disease, or recent injury. Samples were not taken from persons presenting a history of mild illness within the preceding two weeks, or of immunization, severe infection, or contagion within the preceding three months. With two exceptions, the subjects under one year of age were all considered to have been full-term babies. Two babies, one 3 months old and the other 6 months old when the blood was taken, were probably premature at birth. A few persons who had minor injuries, such as blisters or scratches of the hands or feet, were included. A Wassermann test was done on the serum of each child from the institutions, and those few with a positive test have been omitted from the present study. The majority of the children had also been tested with tuberculin at regular intervals while in the Homes. A few (eight) positive tests were obtained, but inasmuch as these showed no clinical or x-ray evidence for active tuberculosis, they have been included.

It is conceivable that each disease to which a child becomes immunized might leave a permanent record of some increase in the total plasma globulin, since the antibodies are found in this fraction. Complete histories were not available on the persons of this study, and therefore, no attempt has been made to classify them on this basis.

Most of the blood samples were taken during the morning. With older children and adults, the majority of the samples were obtained from one-half to two and one-half hours after the usual breakfast. Twenty-six analyses on children between 3 and 9 years of age were made on bloods taken after a fast of twelve hours. No consistent difference was found in any of the protein fractions between the children who had fasted and other children of the same age. Similar findings have been reported by other workers.²⁻⁷ With the small infants, blood samples were also obtained at varying periods of time after feeding. No separation has been made between those who were entirely breast fed and those who received supplemental feedings. In the period from the third day of life to the end of the first month, 90 babies were known to be entirely breast fed, and 15 received one or more supplemental bottle feedings each day. After the first month most of the babies were wholly or partly bottle fed. The small number of bottle-fed babies in the first month of life and of breast-fed babies in the older age groups makes it impossible for us to say with certainty whether the type of feeding is a factor in determining the plasma protein level in infancy; however, no definite association between the type of feeding and the levels of the different protein fractions has been observed in our series. This is in contrast to the work reported by Ujsaghy,⁸ in which lower values for the total plasma protein were found in breast-fed infants as compared with artificially-fed infants of the same age.

Blood samples were taken from the external jugular, the femoral, or the scalp veins in the small infants, and from the arm or hand veins in the larger children and adults. In taking the blood, a minimum amount of stasis was used. The blood sample (2 to 4 c.c.) was placed immediately in a tube containing a slight excess of dry heparin (about 0.5 mg.), mixed, and centrifuged in a stoppered tube as quickly as possible. The plasma was separated usually within one hour from the time the blood was taken, and in all cases, within three hours.

RESULTS

Variation in the plasma concentration of the different protein fractions has been determined within groups of similar subjects. In addition, we have attempted to determine the association, if any, between the different protein concentrations and the factors of age, sex, and season of the year. The series of 566 determinations on 547 persons is made up of 303 determinations on males and 263 on females. These are distributed equally throughout the entire age sequence, except in the range above 20 years, in which the females are predominant; and at 11 years and below 6 months, where the number of males is in excess. The blood samples have been separated into two groups according to the season in which they were done: "summer" extending from April 1 through October 31, and "winter," from November 1 through March 31. In the age period from one month to 6 months, the grouping according to season is uneven. From 6 months to 12 years the analyses are more evenly divided between winter and summer for each age interval and for each sex. For the group from 12 to 20 years, most of the analyses were done during the winter, and from 20 to 40 years, in the summer. The complete distribution of the analyses is summarized in Table I.

TABLE I

DISTRIBUTION OF ANALYSES ACCORDING TO SEASON OF YEAR, SEX, AND AGE OF PERSONS

AGE	NUMBER OF ANALYSES			
	MALES		FEMALES	
	WINTER	SUMMER	WINTER	SUMMER
Birth to 15 days	27	18	16	13
15 days to 31 days	19	15	8	11
1 month to 6 months	34	9	20	6
6 months to 4 years	20	26	22	18
4 years to 8 years	16	25	14	29
8 years to 12 years	22	26	12	25
12 years to 20 years	25	15	34	8
20 years to 40 years	2	4	6	21

Limitations of space prevent a detailed presentation of data; however, these have been analyzed by accepted statistical procedures (Mainland⁹) and the significant findings are given.

Albumin.—The albumin fraction shows no significant variation between the sexes, nor with the height, weight, or body surface of the subjects, but it does vary with age and with the season of the year. During the first month of life the albumin is low, the mean value being 3.79 Gm. per 100 c.c., with a standard deviation of ± 0.33 Gm. There is no apparent change with age at this early period, but the variation between different babies of the same age is large. At about one month a rise in the albumin with increasing age becomes apparent. This continues until the "adult" level is reached, sometime between 6 months and 1 year, after which there is no further significant change with age. As pointed out, the babies in our series were predominantly breast fed in the first month of life and bottle fed after this age. It, therefore, appears possible that the increasing plasma albumin concentration may be associated with the change in diet and may not be entirely referable to age. A consideration of the 90

breast-fed and 15 bottle-fed infants under one month of age gives no indication of a relationship between the plasma albumin level and the type of feeding; however, a larger group of infants must be studied before such a relationship can be determined definitely. In our series there is an apparent rise in the plasma albumin level between the ages of 13 and 20 years old. This may result from the fact that this group of analyses was done during the winter, and the rise in values may be ascribed to seasonal variation rather than to a change with age. The mean "adult" level is 4.70 Gm. per 100 c.c., with a standard deviation of ± 0.32 Gm.

Chart 1.—A scatter diagram of albumin, expressed as grams per 100 c.c. of plasma, referred to age. The unbroken line indicates mean values; the region between the broken lines is that included within plus and minus two standard deviations from the mean.

We have determined the trend of values during the period of change. This is shown graphically in Chart 1, together with the values for both younger and older persons. It can be seen that the spread covered by two standard deviations, including about 95 per cent of the cases, is very large for all ages. This spread is made up of two components, the true biologic variation and the variation caused by chance errors in the analytic procedure. The true biologic variation has been calculated as follows:

$$\begin{aligned}
 \text{S.D.}_B &= \sqrt{(\text{S.D.}_T)^2 - (\text{S.D.}_M)^2} \\
 &= \sqrt{0.32395^2 - 0.07705^2} \\
 &= \sqrt{0.099007} \\
 &= \pm 0.314
 \end{aligned}$$

The symbol "S.D." represents the standard deviation, and the subscript letters "B," "T," and "M" refer to the deviation characterized as biologic, total, and measurement, respectively. It is seen that the true variation between individuals is large, even after allowing for the increment caused by errors of measurement. By means of longitudinal studies we hope to determine whether this wide spread indicates that the plasma albumin concentration varies widely in a given person from time to time, or maintains itself within the individual, at a high or low level in relation to other persons.

The albumin analyses have been studied with respect to seasonal variation. In the series of 127 babies up to one month of age, there is no significant difference in the plasma albumin level at different seasons of the year. For persons over 3 years of age, 142 winter samples give a mean value of 4.83 (S.D._r = ± 0.30), and 167 summer samples show a mean of 4.59 (S.D._r = ± 0.31). Although this difference is not great, the probability that it would occur by chance alone is much less than 1 in 100. Chart 2 shows the frequency distribution of albumin values in the two groups. With the data available we have not been able to determine at what point between one month and 3 years of age the seasonal variation appears.

Chart 2.—Winter and summer frequency polygons of albumin values in 309 analyses on individuals over 3 years of age.

Bazett, Sunderman, Doupe, and Scott¹⁰ have presented evidence to show that during the transition from winter to summer there is an increase in blood volume in human subjects and a corresponding decrease in total plasma protein concentration. As the warmer temperature is maintained, the proteins increase until the initial level is reached. During the transition from summer to winter, the reverse set of changes takes place. It might at first seem that this type of mechanism could account for the seasonal variation in albumin which we have observed, since our "summer" group would, to a large extent, include the transition from winter to summer, and the "winter" group would demonstrate the opposite change. However, since the globulin and fibrinogen have not shown a seasonal variation similar to that observed in the albumin fraction, the picture is more complex than one of simple dilution and concentration of the plasma.

Yosida¹¹ has studied rabbits with respect to the seasonal variation in certain plasma constituents. Although it is difficult to interpret his findings in terms of absolute values for the protein constituents, the figures given should be comparable within themselves. His results on this species of animal show a higher albumin during the summer months than during the winter. This is in direct contradiction to our results in which the lower albumin values occurred during the summer. It seems possible that different species of animals might respond differently to temperature changes. It is also possible that the variation which we have observed may be the result of changes in diet and living habits rather than temperature changes, whereas in the case of rabbits, the diet, activity, and living conditions are more subject to control.

Chart 3.—A scatter diagram of globulin, expressed as grams per 100 c.c. of plasma, referred to age (see legend of Chart 1).

Globulin.—The plasma globulin concentration has been found to vary with age, as shown in Chart 3, but it does not vary with sex or size of the person, nor with the season of the year. At birth, and for the first week of life, the globulin is present in a mean concentration of 1.66 Gm. per 100 c.c., with a standard deviation of ± 0.29 . Between the first and the fifth week the value falls to 1.31 Gm. per 100 c.c. ($S.D._T = \pm 0.25$), where it is maintained until the age of about 6 months. At about 6 months a gradual rise in globulin concentration becomes apparent, and continues to an age of about 4 years, at which time the "adult" level of 2.03 Gm. per 100 c.c. ($S.D._T = \pm 0.34$) is reached. After 4 years, up to 20 to 40 years, there is no significant change in the globulin level. In Chart 3 there appears to be a fall in the globulin in the period between 20 and 40 years. This is probably not a real change, but it may result from the fact that 15 determinations in this age group were obtained on two individuals who have maintained a consistently low globulin over a period of many months.

As was the case with the albumin, the greater part of the variation in values at any age level is apparently a true biologic variation, and not the result of chance errors of analysis. For all persons over 5 years of age the mean globulin concentration is 2.03 Gm. per 100 c.c.; the standard deviation representing biologic variation ($S.D._B$) is ± 0.34 .

The distribution of values shows a definite skew toward the higher globulin concentrations, as shown in Chart 4. Similarly, there are more above the area covered by plus or minus two standard deviations than there are below it, as can be seen in Chart 3. There is no known explanation for this fact; however, it seems possible that in spite of the care exercised in the selection of subjects, a few may have been included who show an elevated globulin as a result of infection or immunization. It is known¹²⁻¹⁵ that the development of antibodies is frequently accompanied by an increase in some fraction of the total globulin, but little is known of the duration of this hyperglobulinemia.

Chart 4.—Frequency polygon of globulin values in 260 analyses on persons over 5 years of age.

Fibrinogen.—The most striking feature of the findings with respect to fibrinogen is a wide scatter of the values in all groups. Chart 5 shows the distribution of values for both sexes graphed with respect to age. From the chart it will be observed that there is a slight tendency toward a higher mean value and greater variation at birth than in the older age groups. This may or may not be a real change; in any event it is probably too small to be of clinical significance, except in so far as it may indicate instability of the plasma fibrinogen concentration in the first weeks of life. After one month there is no significant change with age in the mean level of plasma fibrinogen. This value is 0.21 Gm. per 100 c.c., with a standard deviation (total) of ± 0.0590 . As was the case with the albumin and globulin fractions, the spread in values seems to be due to a true biologic variation, the standard deviation corrected for chance errors of analysis being 0.0585.

In the period up to 5 years of age there is no significant difference between the sexes in the fibrinogen level. After this age the males tend toward lower values, the mean for 123 males being 0.201 (S.D._r = ± 0.054), as contrasted with a mean of 0.218 (S.D._r = ± 0.058) for 136 females. Although this difference is not great, the probability that it would occur by chance alone is between 1 and 2 in 100.

Chart 5.—A scatter diagram of fibrinogen, expressed as grams per 100 c.c. of plasma, referred to age (see legend of Chart 1).

Chart 6.—Frequency polygon of fibrinogen values in 259 analyses on persons over 5 years of age.

The distribution of fibrinogen values about the mean, as shown in Chart 6, shows a skew toward the higher values somewhat similar to that observed with the globulin. This similarity raises a question of correlation between the two

fractions. Chart 7 shows the fibrinogen values in relation to each corresponding globulin value for all analyses on persons over 5 years of age. Although a slight correlation is present, it is to be noted that, with one exception, the fibrinogen values above two standard deviations do not occur in the same persons as those showing globulin values above the two standard deviation range. It seems likely, therefore, that the factor, or factors, producing the skew in the globulin distribution are not the same as those involved in the fibrinogen distribution.

Chart 7.—A scatter diagram of fibrinogen concentration referred to the corresponding globulin concentration in 259 samples of plasma from individuals over 5 years of age.

Ham and Curtis¹⁶ have reviewed the literature with respect to fibrinogen values that have been reported, and have studied this factor in a series of adults under varying physiologic and pathologic conditions. In their discussion these authors state, "Normal pregnancy is the only 'physiological' condition associated with increased fibrinogen concentrations to values of from 350 mg. to 450 mg. *Diagnostically*, therefore, an abnormally elevated plasma fibrinogen concentration in the absence of pregnancy is laboratory evidence for an organic disease process which may be present at the time of observation or which may have terminated several days or weeks before." Our series shows plasma fibrinogen concentrations above 0.4 Gm. per 100 c.c. in 4 of 259 persons over 5 years of age. At the time of the analyses these persons, as stated previously, had had no minor illness (mild colds) in the preceding two weeks, and no serious illness with fever during the preceding three months. One of the four had recovered from pneumonia three and one-half months before the determination was done and may have had an elevated fibrinogen which would extend over this period of time. The other three children had not shown symptoms of any acute or

chronic disease, nor had they been immunized against any disease during an eight-month period preceding the plasma protein determination. One must conclude, therefore, that (1) the findings of Ham and Curtis do not apply to children; (2) allowance must be made for an occasional "normal" plasma fibrinogen concentration above the limits set by these authors; or that (3) the fibrinogen elevation following disease is more prolonged than these authors would lead one to believe. With the data at hand we have been unable to determine which of these three possibilities is the correct interpretation of our results.

Chart 8.—A scatter diagram of total protein, expressed as grams per 100 c.c. of plasma, referred to age (see legend of Chart 1).

Total Protein.—The total protein is frequently determined without separate analysis of the different fractions. This practice leaves much to be desired, since most of the functions of the proteins may be attributed primarily to one or another of the fractions rather than to their combined, total concentration.¹⁷ On the other hand, the determination of total protein is a relatively simple procedure and gives some information of value to the clinician. The total protein reflects the difference between the sexes with respect to fibrinogen and the seasonal variation observed in the albumin; however, the most significant variation is that occurring with age. At birth the total protein concentration is 5.70 Gm. per 100 c.c., with a standard deviation (total) of ± 0.45 Gm. per 100 c.c. During the first month of life the value falls to 5.33 Gm. per 100 c.c. (S.D._T = ± 0.37), after which there is a gradual rise until the adult level of 6.94 (S.D._T = ± 0.47) is reached at about 4 years of age. These changes are shown graphically in Chart 8.

DISCUSSION

Of the many methods used in the study of plasma protein concentrations, the one based upon Kjeldahl analysis has best survived the test of time. This is because the results obtained with this method may be more accurately repro-

duced, and are less subject to errors caused by extraneous factors which may be present, especially in pathologic conditions (see Chorine,⁷ and Myers and Muntwyler²⁰). In the analysis of fibrinogen the values obtained by different methods may be more comparable. Our discussion of albumin and globulin concentrations will be limited to the studies in which a salting-out procedure has been used to separate the fractions, and the analysis has been based upon Kjeldahl nitrogen determination. In some instances, workers have used a factor other than 6.25 to convert the nitrogen content to protein. These figures have been recalculated using 6.25 as the factor in order that all the results may be expressed in the same terms. We do not wish to imply a belief that the different proteins contain exactly 16 per cent nitrogen; however, this nitrogen content is most uniformly assumed, and the protein concentrations calculated upon this basis may be easily corrected at some later date if it is shown that their nitrogen content varies significantly from this value.

Table II gives a summary of albumin and globulin values reported in the literature. Some of these workers have used serum; others have used plasma. In the latter group both heparin and oxalate have been employed as anti-coagulants, and in two instances no statement is made concerning the anti-coagulant. Of the six workers who have analyzed plasma, only two give values for fibrinogen. In three papers the sum of the mean values for albumin and globulin approximates the mean total protein, and it is, therefore, assumed that the so-called "globulin" includes both globulin and fibrinogen. In the report of Muntwyler, Way, Binns, and Myers,²⁷ the mean total protein is greater than the sum of the albumin and globulin, and we have, therefore, assumed that the fibrinogen was determined separately. A variety of salts has been used to separate the albumin and globulin. We have not attempted to analyze the reported values on this basis, but we have included all papers in which a salting-out procedure was employed, irrespective of the salt used. In none of the work to be discussed has any mention been made of the season of the year in which the analyses were done. Seasonal variation in the albumin fraction might, to some extent, account for the disagreement among different workers with respect to this fraction.

The data summarized in Table II cover analyses on 102 adults and 199 children from birth to 15 years. For the entire group of adults the mean albumin concentration is about 4.6 Gm. per 100 c.c., with a range from the low of 3.3 reported by Lewinski²¹ to a high of 5.65 reported by Bruckman, D'Esopo, and Peters.²⁶ This mean value is in relatively good agreement with the mean albumin concentration of 4.7 Gm. per 100 c.c., which we have found in older children and adults, and only the low values reported by Lewinski²¹ and by Linder, Lundsgaard, and Van Slyke²² fall outside the three standard deviation range covered by our series. On the other hand, the mean values reported by the different workers for their respective small groups of persons vary widely with respect to each other and in comparison with our mean.

The globulin analyses reported in the literature cover 54 adults, with a combined mean of about 2.0 Gm. per 100 c.c. and a range from 1.32 to 3.79. This mean value is the same as we have found for older children and adults, as is the total range, except for one high value (3.79) reported by Lewinski.²¹

*Patients have "no apparent abnormality except mild rickets."

†Patients are afebrile convalescents.

‡Numbers in parentheses indicate mean values.

In contrast to this, the mean value of 2.6 Gm. per 100 c.c. for globulin plus fibrinogen, reported in the literature for 48 adults, is distinctly above the sum of our mean values for the two fractions.

Serum analyses have been reported in the literature for 199 children. These results have not been presented for each individual, but for age groups which frequently include periods where we have found the concentration of one of the

fractions to be changing. Thus the mean values for these groups cannot be exactly compared with our series, since we do not know the distribution of persons within the groups that have been reported. In general, the albumin concentrations which have been reported fall well within the range of values covered by our series for corresponding age periods. A notable exception to this is the high mean albumin level of 5.07 Gm. per 100 c.c. reported by Rennie²⁹ in 1934 for 25 children over 1 year old. This is in contrast to our mean of 4.7 for all children over 1 year old, or the mean of 4.83 for the analyses done during the winter months on children of this age group.

Chart 3.—A scatter diagram of albumin concentration referred to the corresponding globulin concentration in 262 samples of plasma from individuals over 5 years of age.

The serum globulin values which have been reported for children tend to be higher than those of our series at corresponding age levels. A possible explanation of this discrepancy might be that some of the children used by other workers, although not acutely ill when the blood was taken, may have shown a mild hyperglobulinemia as a result of recent infection or immunization.

Ham and Curtis¹⁶ have reviewed the literature with respect to plasma fibrinogen concentration in normal persons. In 193 determinations on adults reported by these authors, and in the work reviewed by them, the fibrinogen values fall between 0.190 and 0.380 Gm. per 100 c.c., with a mean of about 0.250. These results are essentially the same as those given in Table II, as reported by Lewinski,²¹ and by Wiener and Wiener.²⁴ Our mean value for persons between 3 and 20 years is slightly below this, and our range is somewhat wider, including many values below those found in the literature, and a few which are higher. We have been unable to find any extensive literature covering the plasma fibrinogen concentration in early childhood or infancy. It is

quite possible that our results on persons from 3 to 20 years of age would not represent the values to be expected in persons from 16 to 61 years, the age range studied by other workers. In our series there is an apparent rise in the fibrinogen in the period from 12 to 20 years. This is offset by the low values observed between 20 and 40 years, and the mean for the entire group beyond 12 years is the same as that for children from 3 to 12 years of age. A real tendency toward increasing fibrinogen concentration after puberty can be established only by studies on a larger group of persons. The results reported in the literature may indicate that such an increase does occur.

Chart 10.—A scatter diagram of fibrinogen concentration referred to the corresponding albumin concentration in 259 samples of plasma from individuals over 5 years of age.

We are not satisfied that the ratios of albumin to globulin have sufficient significance to justify including these values in our tables. It is true that plasma and serum protein determinations are frequently reported in terms of the total protein concentration and the ratio of albumin to globulin, the A./G. ratio. With serum analysis this method of recording, although unnecessarily obscure, gives a complete picture, for one can calculate the more significant individual values for albumin and globulin if the total protein and the A./G. ratio are given. When plasma is used, however, confusion arises because some workers include the fibrinogen with the globulin in computing the A./G. ratio, while others do not.

Interpretation of the results of plasma protein determinations, from either the physiological or clinical point of view, is based largely upon the concentration of each separate fraction, with its independent functions, and not upon the ratios between the different parts. Furthermore, in our work with healthy persons, the three major protein fractions have been found to vary independently

of each other, as shown in Charts 7, 9, and 10. Therefore, we believe that the albumin, globulin, and fibrinogen should be treated as separate entities (or systems), and that it is more satisfactory to record in the literature the actual values of the separate protein fractions rather than a ratio between any of the constituent parts.

Boissevain^{18, 19} has recently reported that serum albumin greatly promotes, and serum globulin inhibits, the growth of the tubercle bacillus on artificial media. Should the two proteins be shown to have an antagonistic action in tuberculosis, the A./G. ratio would become of importance in so far as these patients are concerned.

SUMMARY AND CONCLUSIONS

1. A total of 566 analyses of plasma albumin, globulin, and fibrinogen have been made on 547 healthy persons from birth to 39 years of age.

2. The protein fractions have been separated by salting-out with sodium sulfate and analyzed by a micro-Kjeldahl procedure.

3. Each of the protein fractions undergoes a change with age in early infancy and childhood. These changes have been defined.

4. The plasma albumin concentration in persons over 3 years of age is higher in the winter than in the summer months. This seasonal variation does not appear in the other fractions.

5. In persons over 5 years of age the plasma fibrinogen tends to be higher in females than in males.

6. In normal persons the albumin, globulin, and fibrinogen vary independently.

7. No correlation has been found between any of the protein concentrations and the time elapsing after the ingestion of food.

8. There is no correlation between any of the protein concentrations and the height, weight, or body surface of the individuals.

BLOOD FROM THE EAR LOBE*

PRELIMINARY REPORT

G. BRÜCKMANN, PH.D., TEL AVIV, PALESTINE

IT SEEMS generally accepted that, under standard conditions, practically identical hemoglobin values are obtained from venous and peripheral blood. A closer review of the literature, however, reveals that this view is based in most cases only on comparison of venous blood with blood from the finger tip. Only a few investigators have worked with blood from the ear lobe as representing the peripheral sample, and have found no significant differences for hemoglobin or red blood cells (Bürker,¹ Yarbrough,² Foord,³ Reichel and Monastero,⁴ Price-Jones and co-workers⁵).

During hematologic work at this laboratory concerned with the establishment of standard red blood cell values for Palestine and the study of seasonal influences on these values, the usually taken venous samples were—very occasionally—replaced by samples from the ear lobe; in each of these cases, abnormally high hemoglobin figures were observed. A reinvestigation of the question seemed, therefore, advisable, in spite of the fact that it appears to be settled.

EXPERIMENTAL

As mentioned this study was undertaken as a corollary to standard work, which has been carried out along the internationally adopted lines of such investigations and will be described in detail in a forthcoming publication. If not otherwise stated, the subjects comprised healthy adults between 20 and 40 years of age, presenting themselves before breakfast or four hours after a meal. Blood was taken from the cubital arm vein without tourniquet, Liquoid Roche† being used as the anticoagulant, which, like heparin, causes no shrinkage during the hematocrit determinations.

After wiping the finger pulp and the ear lobe with a little ether, the peripheral samples were simultaneously taken by puncture with a spring lancet, care being taken to avoid squeezing or cyanosis. If only hemoglobin was determined, no anticoagulant was used; otherwise approximately 0.5 c.c. of peripheral blood was collected in small vials prepared with the anticoagulant, as described by Andresen.⁶

Hemoglobin was determined spectrophotometrically after reduction with sodium hydrosulfite ($\text{Na}_2\text{S}_2\text{O}_4$) according to Heilmeyer,⁷ using a Leitz extinction photometer with screen 570 $\text{m}\mu$. This method, which has also been used by Bürker¹ and Williamson,⁸ has proved, after standardization, very satisfactory in our hands. To demonstrate the accuracy of the method, the results of 10 *independent* determinations on the same blood sample are given:

40	Lev	15.7		17.0	

Mean value: 15.96 grams per cent. Standard deviation: 0.44. Standard error: 0.14. Coefficient of variation: 2.78.

RESULTS

Table I gives the results of the simultaneous determinations on venous and peripheral blood, obtained throughout the year. Ten additional comparisons of venous and finger tip blood are for the sake of brevity not listed in the table, but are included in the statistical evaluation given in Table II.

TABLE II

STATISTICAL EVALUATION OF 30 COMPARISONS OF VENOUS AND FINGER-TIP BLOOD

SOURCE	MEAN VALUE	STANDARD DEVIATION	STANDARD ERROR	COEFFICIENT VARIATION	DIFFERENCE OF MEANS	STANDARD ERROR OF DIFFERENCE
Venous	14.40	2.00	0.365	13.9	-0.25	0.52
Finger tip	14.15	2.06	0.376	14.6		

Table II also shows the evaluation of 30 simultaneous measurements of venous and finger-tip blood, obtained from 27 persons (14 males, 13 females), 25 of them healthy ones. The difference of the mean values of -0.25 Gm. is by far too small to be statistically significant. This would be the case only if it were more than twice its standard error (Fisher⁹). Ten of the 30 cases gave identical values; in 5 cases the finger-tip values were higher; in 15 cases they were lower than the venous ones.

TABLE III

STATISTICAL EVALUATION OF 40 COMPARISONS OF VENOUS AND EAR LOBE BLOOD

SOURCE	MEAN VALUE	STANDARD DEVIATION	STANDARD ERROR	COEFFICIENT VARIATION	DIFFERENCE OF MEANS	STANDARD ERROR OF DIFFERENCE
Venous	14.03	1.96	0.310	14.3		
Ear lobe	15.38	2.14	0.338	13.9	+1.35	0.46

Table III shows the evaluation of 40 simultaneous measurements of venous and ear lobe blood. These were carried out on 34 persons (12 males, 22 females), 4 of them suffering from anemia. The difference of mean values, $+1.35$ Gm., is nearly three times as great as its standard error and must, therefore, be considered statistically significant. In 3 cases both values were identical; in one case the ear lobe contained less, in 36 cases, it contained more hemoglobin than the arm vein. On the average, the ear lobe values are 10 per cent higher than the venous ones.

It should be emphasized that the manner in which the blood was taken from the ear lobe seemed to be without influence, as could be observed in separate experiments. The same high values were obtained whether a deep puncture wound with consequent free flow was made, or whether the blood was obtained by repeated squeezing. No change in the picture was seen when the ear blood was taken first, and the venous sample after a few minutes interval. Seasonal influences seemed likewise without effect. More than half of the trials were carried out during the winter and spring season, whose climatic conditions do not show very marked difference from those of American and European countries of the moderate zone.

COMMENT

Differences between venous and peripheral blood under standard conditions have so far been reported only in the case of pernicious anemia by Duke and Stofer,¹⁰ who found higher values in the ear lobe. During the first days or weeks of life higher hemoglobin, red blood cell, and cell volume values were likewise observed by several authors in peripheral blood from the heel (e.g., Andresen and Mugerage¹¹). The notorious high peripheral values in shock, caused by blood concentration, need scarcely be mentioned here.

The fact that such differences also exist in the healthy (and anemic!) adult in the case of the ear lobe should discourage the practice of taking blood from this source for hematologic diagnosis, a practice which is still used by a considerable number of physicians throughout the world. It further offers a possible explanation for the fact that the hemoglobin values in Williamson's⁸

classic investigation are uniformly about 10 per cent higher than those obtained by the majority of all other workers. Williamson had been working with blood from the ear lobe.

It seems conceivable that stasis in the capillaries and subsequent changes in the blood composition may more easily occur in the ear lobe than in the finger pulp. For a better understanding of the phenomenon, however, it is imperative to add red blood cell and hematocrit determinations to the hemoglobin values reported in the present paper. Work on this line is now in progress, and it can already be stated that a tendency for macrocytosis prevails in the ear lobe blood. It would be worth while to investigate if this also applies to body blood deposits.

SUMMARY

Venous blood has been compared under standard conditions with peripheral blood from the finger tip and the ear lobe.

No significant differences exist between the hemoglobin content of venous and finger-tip blood. Blood from the ear lobe, however, contains significantly more hemoglobin and should, therefore, not be used for diagnostic purposes.

I wish to express my gratitude to Dr. I. L. Fisher for his helpful advice and criticism throughout this study.

THE MEASUREMENT OF INTRAVENOUS BLOOD SUGAR CURVES*

BENGT HAMILTON, M.D., AND A. F. STEIN, M.D.
CHICAGO, ILL.

THE blood sugar curve, obtained after the administration of glucose, is a clinical laboratory test frequently employed, but only rarely giving any clear-cut information, except in cases of markedly abnormal carbohydrate metabolism. Although it is well known that there are great normal variations in blood sugar curves, variations noted when examining a number of persons, as well as one and the same person on different occasions, there is no simple way of describing these variations.

The following report describes a method by which the intravenous blood sugar curve may be characterized by a single figure. The method is based on the fact that, although a curve is difficult to describe, it is easy to measure the slope of a straight line. Many curves may be considerably straightened out by plotting on logarithmic paper; often this is true of the intravenous blood sugar curve to a very surprising degree, especially in the middle part of the curve, where the values fall in the range of normal postabsorptive values (from about 200 to 100 mg. per 100 c.c.). This is, probably, the most important part of the curve. In the higher ranges, never reached under normal conditions, it is possible that special mechanisms come into play (for instance, excretion of sugar through the kidneys). Toward the end of the curve, at values of about 100 mg. per 100 c.c., we might expect various mechanisms for stabilizing the blood sugar at normal values to become active. In the middle range, however, we would observe and study the normal mechanism for removal of excess carbohydrate from the blood after ingestion of carbohydrate, and it is interesting that it is in this range that the logarithmic curve so often forms a straight line.

METHOD

The blood sugar values are plotted on semilogarithmic graph paper, and the part which forms an approximately straight line is noted. In questionable cases, where it is difficult to decide how much of the curve is approximately straight, the decision is not of very great importance, as long as the selected part includes most of the values between 200 and 100 mg. per 100 c.c. As will be shown later, including one value more or less will not greatly change the final result. The logarithms of the blood sugar values forming the end points of the selected part of the curve are then obtained, with two decimals, from a table or slide

*From the Department of Pediatrics, University of Illinois College of Medicine, and the Children's Division of Cook County Hospital, Chicago.

This work was supported by a grant from Mead Johnson & Company, Evansville, Ind.
Received for publication, August 4, 1941.

rule. The difference between these two logarithms, divided by the time elapsed between these two points of the curve, is an approximate measure of the slope of the curve.

TABLE I

MIN. AFTER INJECTION	BLOOD SUGAR	LOG BLOOD SUGAR	CHANGE IN BLOOD SUGAR
2	280	2.45	
15	220		60
30	161		51
45	124		37
60	99	2.00	25
75	101		+2
90	98		3

Table I gives the blood sugar values obtained in Case 2 (third from the left in the second row in Fig. 1). An approximately straight line is formed between the values 280 (first value) and 99 (fifth value). The difference between the logarithms of these two values is $2.45 - 2.00 = 0.45$. The value 280 was obtained two minutes after the injection of glucose; the value 99, sixty minutes after the injection; the elapsed time is, therefore, 58 minutes. In this period of time the logarithm of the blood sugar decreased 0.45. In one minute, then, it decreased on the average 0.00776. This value, 0.00776 per minute, is a measurement of the slope of the logarithmic curve. However, a decrease of the logarithm of the blood sugar of 0.00776 per minute is the same as if the actual blood sugar value had been divided by 1.0181 each minute. Dividing by 1.0181 is the same as multiplying by 0.9823. In other words, the blood sugar at the end of each minute is in this case on the average 98.23 per cent of what it was at the beginning of the minute, which is a decrease of about 1.77 per cent. This figure, 1.77 per cent per minute, is the measure of the rate of decrease of sugar in the blood in this case. Fortunately, this rather complicated calculation made to arrive at this figure is not necessary. If the slope of the logarithmic curve (in this case 0.00776) is multiplied by 230, we will always arrive at approximately the same result as that obtained in the above calculation.* In this case, we get 1.78 per cent per minute by using this method, while the more elaborate calculation resulted in the value 1.77 per cent per minute. As the accuracy of the method justifies the inclusion of only one decimal, the difference is not important. For practical purposes it is sufficient to say that the rate of decrease of blood sugar in Case 2 was 1.8 per cent per minute.

It must be very strongly emphasized that this figure, 1.8 per cent per minute, is not the same as 18 per cent in ten minutes, or 180 per cent in one hundred minutes; that is, it is not the same if percentage change is calculated, as is usually done, in per cent of the initial figure at the beginning of the period of change. If, however, the percentage change is calculated in per cent of the geometric mean between the initial and the final figure during the period of change, then it will be approximately correct to multiply per cent per minute by any number of minutes.

*This statement is based on the fact that $\frac{d}{dt}(\log_e y) = \frac{1}{y} \cdot \frac{dy}{dt}$.

The multiplication by 100 is made to change a fraction into percentage; by 2.30, to change ordinary into natural logarithms.

Summary of Method.—Plot the blood sugar curve on semilogarithmic paper (obtainable in most stationery stores). Determine which part of the curve is approximately straight. Obtain from a table or slide rule the logarithms (with two decimals) of the two figures forming the beginning and end of the straight part of the curve. Take the difference between these two logarithms, divide this difference by the number of minutes elapsed between the two blood sugar determinations, and multiply the result by 230. The figure obtained is the average rate of decrease of the blood sugar in per cent per minute.

Fig. 1.—Intravenous blood sugar curves from approximately normal persons plotted on logarithmic paper. The part of the curve used for estimating the slope is marked by arrows. The figures indicate the slope expressed in per cent per minute decrease.

We have made intravenous blood sugar curves on a number of patients with miscellaneous disorders, all children; old burns, kept in the hospital for grafting; patients with gonorrheal vaginitis; fractures; patients with bronchiectasis. Some of these have received a diet high in carbohydrate, others a diet low in carbohydrate; many were tested on both diets. We shall not give the data as to the composition of the diet, since the lack of a metabolism ward made it quite certain that the diets were only approximately followed. The diets as offered had a ketogenic-antiketogenic ratio of about 0.25:1 for the high carbohydrate diet, 2:1 for the low carbohydrate diet. All we can definitely say is that these two diets were very different in their carbohydrate content.

The technique of the intravenous test is important for the interpretation of the curve. It goes without saying that the amounts of sugar given should be

strictly standardized. In our tests we have given 0.5 Gm. of glucose per kilogram of body weight in a 20 per cent solution (in normal saline). The amounts of dextrose injected have a marked effect on the curve.¹ In some cases we have given smaller amounts and found that on these smaller amounts the curves tend to be irregular and difficult to interpret. The time used for injection should be made as uniform as possible by using the same size intravenous needle and the same pressure in every case. We have used a No. 18 intravenous needle and a salvarsan tube with very rapid drip at a distance of six feet from the floor. In this manner, the injection was usually completed in less than one minute. According to Tunbridge and Allibone,¹ small differences of two to four minutes in the time used for injection are of no importance for the result.

RESULTS

In Fig. 1 are plotted on logarithmic paper our 24 patients, more or less normal, on a high carbohydrate diet. The curves are ranged according to the steepness of the slope, and the figures above the curves indicate the steepness in terms of per cent decrease per minute. The part of each curve chosen for the calculation of the slope is indicated by the arrows. It may seem as if this part, in some cases, was rather arbitrarily chosen, but as has already been pointed out, it makes very little difference in the result of the calculation if one only adheres to the principle of (1) choosing as straight a part of the curve as possible, and (2) in questionable cases to include approximately the range from 200 to 100 mg. per cent. In Case 20, for instance, it may seem questionable whether to calculate from the second or the third value; calculating from the second, one obtains a slope of 1.9 per cent per minute; calculating from the third, the value obtained is 1.7 per cent per minute. In Case 3, calculating from the second value the slope is 1.4, from the third value, it is 1.2 per cent per minute. Going over a number of curves in this manner we have found that the error of the method is, approximately, 0.2 per cent, as far as the calculation of the slope is concerned. It seems likely that if we assume a total error of twice as much, ± 0.2 per cent, we shall not overestimate the accuracy of the method. That would mean that values more than 0.4 per cent apart should be considered as showing a real difference. The total range of our values is from 0.9 to 3.8 per cent per minute (a difference of 2.9 between the highest and the lowest value), and with an error of 0.4 per cent we would, then, be justified in recognizing seven different degrees of steepness. This, it seems to us, is a worth-while refinement on the usual method of designating the curves as "steep," "normal," or "flat."

In Table II may be seen the distribution of the values for the slope of the curve (the removal rate of sugar from the blood) in patients on a high and on a low carbohydrate diet. (Four more curves are included than in Fig. 1, the additional four being repeated curves on cases previously tested.) The table shows how on the high carbohydrate diet the most common removal rate was between 1.5 and 1.9 per cent per minute (10 cases), while on the low carbohydrate diet the most common rate was between 1.0 and 1.4 per cent per minute. A very interesting fact stands out: There was considerably more variation

between the cases on a high carbohydrate diet than between those receiving a low carbohydrate intake (16 cases were tested on both diets; the difference in variability may, therefore, hardly be ascribed to a difference in case material). This is all the more striking, since we feel sure that the low carbohydrate diet was more often broken than the high carbohydrate diet. The findings seem to indicate that when the carbohydrate metabolism is understimulated (low carbohydrate diet), the reaction to a sudden demand on this metabolism (intravenous injection of glucose) is very much the same in all persons; while there seems to be considerable individual variation in the response when the metabolism has previously been stimulated by a high carbohydrate intake. We may also conclude that if we plan to study individual variations in carbohydrate metabolism, it seems more likely that a high carbohydrate intake will bring out such variations than a low carbohydrate diet. In some persons, tested on both diets, the difference in response was very marked; in others the difference was small. The difference in response was nearly always due to differences in the response to the high carbohydrate diet, since the removal rate on the low carbohydrate diet was very much the same in all cases.

TABLE II

DISTRIBUTION OF PER CENT PER MINUTE DECREASE OF BLOOD SUGAR AFTER
INTRAVENOUS INJECTION

CARBOHYDRATE DIET	NUMBER OF CASES					
	LESS THAN 1.0	1.0-1.4	1.5-1.9	2.0-2.4	2.5-2.9	3.0+
High	-	4	10	5	5	4
Low	1	17	7	-	-	-

TABLE III

CASE NO.	REMOVAL RATE AFTER 3 DAYS ON HIGH CARBOHYDRATE DIET; % PER MIN.	REMOVAL RATE AFTER DIET CHANGED TO LOW CARBOHYDRATE	
		AFTER 2 DAYS	AFTER 5 DAYS
44	1.7	1.0	1.0
45	2.5	1.4*	1.0
46	1.6	1.0	1.2
47	2.5	1.8	1.2

*Technique not quite good.

It is, of course, a well-known fact that the preceding diet is of great importance for the outcome of the blood sugar curve. According to Tunbridge and Allibone,¹ the patient should be on the diet two weeks before the test is made, a condition hardly possible to fulfill in clinical practice. To judge from our findings, the diet is of more importance in some persons than in others. Not only, as mentioned above, that some persons respond very strongly to a high carbohydrate diet (steep curves) while in others the response is much less marked; but it seems also that the maximum effect of a change in diet is obtained sooner in some persons than in others. In Table III may be seen the result obtained by suddenly changing the diet in four cases. In those two (Case 44 and Case 46) where the removal rate was about average on a high carbohydrate diet, no more effect of the change was seen after five days than

was already present after two days. In the two remaining cases, however, the removal rate was rather rapid on the high carbohydrate diet, and in these two cases the effect of this diet seemed to last longer. If the values obtained after only two days on a low carbohydrate diet had been accepted as final, one would, obviously, have obtained an erroneous impression as to the speed of removal on this diet. For this reason, we have included in our table only the cases where the diet had been given at least four days previous to the test.

COMMENT

A simple way of measuring the intravenous curve is that used by Crawford,² who classifies the curve according to the time it takes after the injection for the blood to reach normal levels. We are of the opinion that the intravenous blood sugar curve deserves a somewhat more accurate method of measuring than is obtained in that manner. For instance, measured according to Crawford, the five first curves in Fig. 1 would be all the same, while a brief look shows that the fifth (Case 21) is steeper than the first (Case 3). The method also would indicate differences where, in our opinion, none exist, as for instance between the fifth case in the first row (Case 21) and the sixth case (Case 36). The former (Case 21) reached the level of 100 mg. in about sixty-seven minutes; the latter (Case 36), in about fifty-five minutes. According to our calculation, the curves are about alike and the difference obtained by the other method of estimation is due entirely to the fact that the curve of Case 21 starts at a higher level than that of Case 36. Compare also the two last curves in the diagram, Cases 6 and 10. Here again, the curves would be very different according to Crawford, but about the same according to our method of measuring. It seems questionable to us whether the absolute height to which the curve rises—which plays such an important role in the method of Crawford—is not much less important than the steepness of the slope, which is the only characteristic measured by our method. In any case, the steepness should be measured; then, as a second characteristic, may, perhaps, be added the maximum rise.

Ross and Tonks³ are, in our opinion, using a somewhat too complicated method for measuring the intravenous curves. These authors measure the surface area under the curve by means of a planimeter. In addition to this being a somewhat elaborate method, it also seems to us that from a mathematical standpoint the differential of the blood sugar curve, which is determined by our method, has more meaning than the integral, determined by Ross and Tonks.

Although the purpose of our study was to find a practical method of measuring variations in the intravenous blood sugar curve, a fact of more theoretical interest became apparent from our data: Whenever the intravenous curve forms a straight logarithmic line, the rate at which the sugar is being removed from the blood at a given moment is directly related to the amount of sugar present in the blood at that moment; being always the same percentage of the amount of sugar present.

Another interesting fact is that in at least ten of our curves an approximately straight line slope changes suddenly into a horizontal line (L-shaped curves). This indicates that at a given level of blood sugar the removal of sugar from the blood suddenly stops, or, which is more probable, at a given

level sugar begins to enter the blood at the same rate as it is removed. If the latter is true, we would, then, have a method of calculating the rate at which—in a given individual—the sugar enters the blood at a given time; in other words, the rate of flow of sugar from stores and alimentary tract. For instance, if a curve with a slope of 2 per cent per minute suddenly becomes horizontal at the level of 100 mg. per cent, we might assume that this equilibrium is accomplished by an inflow of 2 per cent per minute, or approximately 2 mg. for every 100 c.c. of blood. If such a person had 10 liters of blood, he would have to consume, on the average, 12 Gm. of sugar per hour to maintain the rate of supply of sugar to the blood. It may thus be seen that the assumption we have made leads to rather reasonable figures for daily carbohydrate intake.

SUMMARY

A method is described by which the slope of the intravenous blood sugar curve may be calculated in a simple manner and described by a single figure.

By using this method, it was shown that the slope of the intravenous curves was surprisingly constant when the patients received a low carbohydrate diet; on a high carbohydrate diet the patients showed considerable individual variations.

THE USE OF DIHYDROTACHYSTEROL IN PARATHYROIDIC TETANY*

REPORT OF A CASE

FLOYD E. HARDING, M.D., LOS ANGELES, CALIF.

THE occurrence of tetany following removal of the thyroid gland with destruction or loss of the parathyroids is unusual, owing to the improvement in surgical technique that has taken place. There are normally four parathyroid glands, two on each side of the thyroid, but their number and location vary considerably due to defects in embryologic development. Because of this anomaly and their small size, they are often partly removed. Hypertrophy of the remaining glandular tissue usually brings about a cure in a few months. In rare instances so much gland tissue has been removed that tetany becomes a permanent condition. The case reported here is of this type, since regeneration did not occur after one and a half years, and the treatment presented an ideal clinical subject for observation of the effect of a new drug.

*From the Department of Medicine, Ross-Loos Medical Group, Los Angeles.
Received for publication, November 25, 1940.

Dihydrotachysterol is made from tachysterol, a by-product of the irradiation of ergosterol with ultraviolet light. It will raise the blood calcium to normal or even above normal when given by mouth, and for this reason, has an advantage over parathyroid extract, which is given hypodermically. The effect of parathyroid extract is of short duration, not over forty-eight hours. When dihydrotachysterol is used, the blood calcium does not begin to rise until after forty-eight hours, reaches a maximum in about one week, and decreases in one to three weeks after its use is discontinued. When too much dihydrotachysterol is used, the patient complains of asthenia, nausea, vomiting, headache, stupor, thirst, or skin rash. The method of management of a patient under this treatment, with frequent check on the blood chemistry or urine, is described by Albright.² The urine test can easily be performed by the patient at home. Sulkowitch reagent is added to urine, and the observation of a fine, white precipitate with a normal excretion of calcium is indicative of a normal blood calcium. If the solution remains clear, hypocalcemia is present. In hypercalcemia the solution becomes milky with increased output of calcium.

Hypoparathyroidism causes low blood calcium, high blood phosphorus, decreased excretion of calcium in the urine, and positive calcium balance (less excretion than intake). What becomes of the calcium that is ingested is a mystery, since density of the bones is not evident on radiologic examination. It has been suggested that the calcium is deposited in the tissues. As the blood calcium goes down, the phosphorus goes up, and vice versa, so that it is necessary to decrease the blood phosphorus by a diet low in phosphorus in order to facilitate raising the calcium. While dihydrotachysterol raises the blood calcium, it does not mobilize the calcium in the blood by removing it from the bones, as is the case when parathyroid extract is used. Dihydrotachysterol will not prevent or cure rickets as irradiated ergosterol does, so that the latter is necessary to improve bone quality. It is better, therefore, to combine vitamin D, calcium, and dihydrotachysterol in the treatment of parathyroprivic tetany.

The dosage of dihydrotachysterol is not well established. It varies with the amount of the gland removed and the degree of regeneration. If all parathyroid tissue has been removed, the dosage is more constant. Adams¹ reported a case of short duration following subtotal thyroidectomy in which the patient was symptom free on 1 c.c. twice a week. Newman⁵ reported a case of parathyroprivic disease with tetany of seven years' duration in which 1 c.c. of dihydrotachysterol daily was necessary in spite of the fact that the blood calcium ranged from 8 mg. to 12.6 mg. for each 100 c.c. of blood before treatment. The use of the drug in idiopathic tetany^{3, 4} and scleroderma⁶ is somewhat different from that following accidental removal of the parathyroids.

The case presented here is unusual and interesting for the following reasons: (1) absence of parathyroid tissue and the appearance of tetany any time treatment is discontinued; (2) dosage of dihydrotachysterol; (3) persistence of considerable laryngeal stridor even with a blood calcium of 9 mg.; (4) further improvement of laryngeal stridor with thyroid extract; (5) decalcification of jawbone; and (6) injury to the recurrent laryngeal nerve.

REPORT OF CASE

The patient, a schoolteacher, aged 46 years, was referred for treatment on August 26, 1939. She complained of cramps in her arms and hands. During the spasms she could not straighten out her hands and fingers. There was extreme weakness with the attacks which were relieved only by an injection of parathyroid extract about every other day. She talked mainly in a whisper, but occasionally made rather high-pitched noises. Nervousness and irritability were pronounced. Her ankles were slightly swollen.

She gave a history of thyroidectomy in July, 1928. In June, 1939, a large adenoma was removed from the region of the right upper part of the thyroid, in which was imbedded the right upper parathyroid. The tetany first appeared following the latter operation. Other operations included tonsillectomy, appendectomy, uterine suspension, and a few dental extractions.

She stated that the goiter had originally appeared during puberty. Following thyroidectomy she felt well until 1932, when she had a nervous breakdown. The history from 1932 to 1939 was supplied by several doctors who had treated her during that period. The following basal metabolism readings were recorded during these years: 1932, +31, +24, +10, +15, +28, +30; 1933, +26, +26; 1934, +25; 1935, +14, +14, +35; 1936, +31, +39; 1937, +19, +19, +24, +28; 1938, +30; and 1939, +35, +44. The Wassermann test, urinalysis, and blood count were normal in 1934. A small mass became evident in the region of the upper half of the right lobe of the thyroid, and continued to increase in size. The patient presented symptoms of exhaustion, nervousness, pounding of the heart, protrusion of the eyeballs, loss of weight, and slight tremor of the fingers. Her pulse rate varied from 100 to 140; her blood pressure was 130 systolic and 75 diastolic. The menstruation was regular every twenty-eight days. The diagnosis was made of chronic nervous exhaustion, with adenoma of the right lobe of the thyroid and mild hyperthyroidism. Removal of the adenoma was advised by several doctors, but the patient preferred medical treatment and was given Lugol's solution, sedatives, and other treatment at various times until she submitted to removal of the adenoma.

Physical examination on the first visit here was essentially normal. The scar on the neck was slightly tender. The pulse rate was 84. Medication for each day consisted of one vitamin ABDG capsule, 6 tablets of calcium gluconate of 15 grains each, 6 tablets of desiccated parathyroid of 0.1 grain each, and 60,000 U.S.P. units of irradiated ergosterol. She was receiving parathyroid injections about every other day.

In September, 1939, dihydrotachysterol, 1 c.c. every three days, was added to the treatment and later increased to 1 c.c. daily, since the blood calcium was still 7.5 mg. for each 100 c.c. of blood. The patient was started on a high-calcium, low-phosphorus diet. The parathyroid injections were decreased to two a week and later to one a week. She began feeling stronger and gaining weight and was advised to start walking for exercise. Her basal metabolism was +12, her urinalysis was negative, and her blood pressure was 88 systolic and 60 diastolic.

In October she was much better, and showed some improvement in the voice and no swelling of the ankles. Since she was markedly nervous it was still necessary for her to rest all the time. With exercise the muscles between the shoulders would cramp, but there was no definite tetany; she had discontinued the parathyroid injections and tablets, as well as the irradiated ergosterol. At night during sleep she made sounds resembling snoring that kept her husband awake. One-half grain of phenobarbital at bedtime was prescribed. Her blood pressure was 98 systolic and 68 diastolic, her blood calcium was 9 mg., and her basal metabolism rate averaged -9.

In November and December she showed general improvement, but as her voice improved the breathing noises at night increased. She tried reducing the dihydrotachysterol from 15 minims to 10 minims daily, but her condition became worse and she had to resume taking 1 c.c. daily. Daily urine tests with the Sulkowitch reagent were started, and there was a fine, white precipitate most of the time, although occasionally the urine was clear or milky. Her blood calcium was 8 mg., her basal metabolic rates were -10 and -25; red blood cells 4,270,000, hemoglobin 74 per cent, and the urinalysis negative. Her weight increased to 147 pounds. The hair on her legs, head, and eyebrows, which had turned white, began to get darker. One-fourth grain of thyroid was added to the treatment.

In January and February, 1940, she showed general sluggishness, with some cramps in the legs and some shortness of breath. Her blood pressure was 100 systolic and 68 diastolic, her blood calcium was 8.5 mg., her pulse rate was 70 to 86, she weighed 151½ pounds. The urinalysis was negative. The thyroid extract was increased to 0.5 grain daily. She discontinued taking vitamin D. By March her voice had improved considerably. It was felt that the recurrent laryngeal nerve had regenerated, but there was now a loud crowing noise on inspiration and shortness of breath on climbing stairs. She stopped taking the thyroid extract, since she thought that she felt better without it. An electrocardiogram showed marked myocardial damage. Urinalysis was normal. She was advised to continue resting and to eat more fruits and vegetables and less of fattening foods. A postcard arrived in April, 1940, stating that she had stopped the dihydrotachysterol for ten days, but had a bad attack of tetany and had to take an injection of parathyroid. She had severe cramps, and could not straighten out her hands. The dihydrotachysterol was resumed.

The patient was not heard from again until July. The drops had been discontinued for three weeks. The tetany with carpopedal spasm had reappeared, and she had difficulty in breathing with loud tracheal stridor. A few injections of parathyroid helped to relieve the cramps, but there was considerable weakness and nervousness. She was placed in the hospital where she remained for two weeks. She made an uneventful recovery on 1 c.c. of dihydrotachysterol daily. Examinations by a surgeon, otolaryngologist, and neurologist were all essentially normal. The vocal cords were functioning normally, and all agreed with the diagnosis of tetany and laryngeal stridor due to parathyroprivia. The eyes were tested and glasses were fitted to correct a slight visual disturbance.

On the day the dihydrotachysterol was resumed, the blood calcium was 5.3 mg.; a few days later it was 7.2 mg., with 6.5 mg. of phosphorus. The hemoglobin was 69 per cent, red blood cells 4,380,000, color index 0.8, white blood cells 9,000, platelets and differential cells normal. The temperature ranged between 97.4° and 99° F., usually slightly subnormal. In August the calcium tablets were discontinued, and two teaspoonfuls of powdered calcium gluconate, three times daily, were given in their place. Marked laryngospasm and tracheal stridor continued in spite of this, although both symptoms improved to some extent. The urine tested with Sulkowitch reagent was always milky. Dental x-ray examination showed some decalcification of the jawbones. A roentgenogram of the spine showed no general decalcification. The blood pressure was 110 systolic and 72 diastolic. The basal metabolic rate was -27.

In September the patient was much better; she looked rested and felt stronger, but she still had dyspnea with loud inspiration noises. When she was asleep, her breathing could be heard all over the house. Menstruation was still regular every month. Foods containing phosphorus were eliminated from the diet. Irradiated ergosterol, 3,500 U.S.P. units, was given after each meal. Blood calcium was 8.5 mg. At the beginning of the second week in September, 1 grain of desiccated thyroid was given daily. Blood calcium was 7 mg., and blood phosphorus was 4.1 mg. The pulse rate was 80, and the blood pressure was 100 systolic and 72 diastolic.

On Monday, September 16, 1940, the patient was feeling much better and started to work. By September 20 she was feeling stronger, although she had finished one week of work. She was breathing easier and with much less noise. Her pulse rate was 80. On September 27 she was feeling very well; she had no dyspnea and no stridor at all when sitting, and only slight musical noise on inspiration during exercise. At the end of the second week of work she felt she had succeeded in her effort to get back on the job. This was the first time she had worked since June, 1939. During October she still continued in relatively good health. Her blood calcium was 8.3 mg. and her blood phosphorus was 5.3 mg.

DISCUSSION

In the case just presented, the laryngeal stridor was the most difficult symptom to overcome. It was necessary to give intensive treatment with a combination of drugs and diet to improve the calcium metabolism before improvement occurred. The dihydrotachysterol relieved the irritability and spasm

of the muscles, and the thyroid improved the muscle tone and use. These two drugs were the most useful in the treatment of the case. It was necessary to keep a close check on the diet. The dosage of all medication essential to create and to maintain a state of good health was larger than expected. The treatment was expensive, since the monthly allowance of 30 c.c. of dihydrotachysterol plus the other drugs averaged about \$20.00.

A milky urine when tested with Sulkowitch reagent did not mean that hypercalcemia was present. When larger doses of calcium were given by mouth to this patient, the urine test was always milky, although the blood calcium was only 8 or 9 mg. for each 100 c.c. of blood. The patient is going to try to take less of the calcium gluconate with the same amount of the other drugs since she is probably taking more calcium than is necessary for maximum improvement. Of course, there is no danger of a high blood calcium if the urine is clear or slightly cloudy. The test is of diagnostic value before treatment, and it can be used during treatment if smaller amounts of calcium are given. When the urine test is milky, a blood test is necessary to determine the exact level of the blood calcium.

SUMMARY

The treatment of a case of parathyroid tetany with injury to the recurrent laryngeal nerve is presented. The recurrent laryngeal nerve regenerated in a few months, but the deficiency in parathyroid hormone continued after one and one-half years. Maximum improvement was brought about only after intensive treatment with a low phosphorus diet, calcium gluconate, irradiated ergosterol, dihydrotachysterol, and thyroid extract. Dihydrotachysterol raised the blood calcium, prevented the tetany, and partially decreased the laryngeal stridor. The thyroid extract raised the basal metabolism and further improved the laryngeal stridor. The minimum dosage of dihydrotachysterol was 1 c.c. daily. There was decalcification of the jawbones, but no general decalcification of the skeleton.

THE COMPARATIVE PHYSIOLOGIC VALUE OF INJECTED CAROTENE AND VITAMIN A*

JANE G. LEASE, PH.D., E. J. LEASE, PH.D., H. STEENBOCK, PH.D., AND
C. A. BAUMANN, PH.D., MADISON, WIS.

MANY workers have observed that carotene or vitamin A may be biologically active when injected into experimental animals (Wollman and Vogliano;¹ Koehne and Mendel;² Wolff, Overhoff, and van Eekelen;³ von Euler and Rydbom;⁴ Rydbom;⁵ Gordon and Titherington;⁶ Chu and Coady;⁷ Laseh;⁸ Greaves and Schmidt;^{9, 10} Guilbert and Hart;¹¹ Wilson, Ahmad, and Majumdar;¹² Phillips and Bohstedt¹³). Parenteral carotene and vitamin A have also been reported to be effective in human therapeutics (Blegvad;¹⁴ Edmund;¹⁵ Bloch;^{16, 17} Buschke;¹⁸ Josephson and Freiburger¹⁹). However, there is also abundant evidence that injected vitamin A is not always efficiently utilized. Funk²⁰ stated that vitamin A given parenterally was without any activity. Wollman and Vogliano¹ observed that repeated injections of cod-liver oil or butter oil were not tolerated well, since no growth resulted until after injections were stopped.

Koehne and Mendel² observed only temporary remission of deficiency symptoms with the accumulation of much foreign fat at the site of injection when butter oil or cod-liver oil were injected into depleted rats. Von Euler and Rydbom⁴ found that 0.050 mg. of carotene injected daily was inadequate for growth in depleted rats, although much smaller amounts given orally were known to restore growth. Chu and Coady⁷ also reported better results with carotene given orally than with that given parenterally. Drummond and co-workers²¹⁻²⁴ failed to find any storage of vitamin A in the livers of rats and cats when carotene, emulsified in glucose solution, was injected intravenously. In one experiment with rabbits, however, some vitamin A was stored. This relative inertness of parenteral carotene has also been observed by Ahmad, Grewal, and Malik²⁵ in their work with rats and dogs.

Furthermore, preliminary experiments of our own indicated that injected carotene was not converted into vitamin A efficiently. Rats with stores of 175 blue units per liver were fed a fat-free diet, and then given intraperitoneal injections of large amounts of an aqueous suspension of colloidal carotene. No vitamin A could be detected in the livers after five weeks, although much carotene was found at the site of injection, adherent to the liver.

Parenteral administration of vitamin A sometimes appears to be indicated in human therapy (Blegvad;¹⁴ Bloch;^{16, 17} Gordon and Titherington;⁶ Edmund

Received for publication, December 4, 1940.

and Clemesen;²⁰ Finkelstone, Howard, and Paris;²⁷ Decourt;²⁸ Buschke;¹⁸ Josephson and Freiburger¹⁹). However, experimental data on the relative efficiencies of the various means of administration are lacking even with animals. We have, therefore, carried out experiments with rats, using several biological criteria, such as cure of ophthalmia, duration of cure, and growth and survival time, together with data on the carotene and vitamin A content of the tissues.

METHODS

Rats 3 weeks old and 35 to 50 gm. in weight were fed a basal ration composed of casein (heated at 95° C. for fourteen days) 18 per cent, Osborne and Mendel salt mixture (as modified by Hawk and Oser²⁹) 4 per cent, brewer's yeast 7.9 per cent, irradiated brewer's yeast 0.1 per cent, hydrogenated fat* 10 per cent, and sucrose 60 per cent. Food and water were given ad libitum throughout both the preliminary and experimental periods. Supplements of carotene or vitamin A were administered when the animals showed a loss in weight and the initial stages of ophthalmia. The supplements were given in the form of colloidal water suspensions or as oil solutions. Both were fed as well as injected. The amounts given ranged from 75 to 1,500 μ g. The volumes of the doses did not exceed 0.25 c.c. for the oil solutions, and 1 c.c. for the colloidal suspensions. A detailed account of the various doses administered is given in the tables of results. In the evaluation of the biological response primary emphasis was placed upon the cure of ophthalmia because of the possibility that repeated injections might interfere with growth.¹ At the end of the experimental period the animals were killed and the tissues were analyzed for carotene and vitamin A.

The aqueous colloidal suspensions of carotene were prepared by slowly adding carotene in acetone solution to hot (90° C.) water agitated with a stream of nitrogen. The preparations were made fresh every three days and filtered to remove visible particles. A similar procedure was used for the preparation of aqueous colloidal solutions of vitamin A. The source of vitamin A was halibut-liver oil.† Its unsaponifiable matter was dissolved in methyl alcohol, chilled to -10° C., and filtered. The filtrate was dried under nitrogen and reduced pressure, then dissolved in acetone, and slowly added to hot (90° C.) water agitated with nitrogen.

For its quantitative determination the carotene was taken up in chloroform, and the intensity of absorption was measured at 485 and 460 m μ in a Bausch & Lomb spectrophotometer. Animal tissues were first dissolved in 8 per cent potassium hydroxide at room temperature overnight, and then 2 volumes of water with sufficient alcohol to make a concentration of 15 per cent alcohol were added. The carotene was extracted with peroxide-free ether, the extracts were washed with water and evaporated in vacuo, and the residue was dissolved in chloroform.

A similar procedure was employed in the preparation of extracts suitable for the determination of vitamin A by the colorimetric method of Carr and Price.³⁰

*A mixture of partially hydrogenated vegetable fats marketed under the trade name "Spry."

†The halibut-liver oil was a commercial brand known as Haliver Oil, furnished by the Abbott Laboratories.

PARENTERAL ADMINISTRATION OF CAROTENE

(a) *Physiologic Requirements*.—When aqueous colloidal carotene was injected in amounts equivalent to 375, 750, or 1,500 μg per rat per week, ophthalmia was cured and growth was restored (Table I). Growth was equally good with injections of 750 or 1,500 μg a week, with an approximate gain of 60 Gm. in weight in five weeks. This was also the rate of growth observed when 75 μg of colloidal carotene were given weekly by stomach tube or when 7 μg of carotene were fed in oil solution by dropper. Thus, the amount of carotene necessary to produce a given biological response may vary by over a hundredfold, depending upon the mode of administration. Lesser amounts of carotene produced lesser gains in weight, e.g., the intraperitoneal injection of 375 μg of colloidal carotene per week resulted in a gain of only 37 Gm. in five weeks, whereas 75 μg per week failed to restore growth, to cure ophthalmia, or to maintain life. At our levels of administration (Table I) no difference in the response of animals injected subcutaneously or intraperitoneally was noted. Furthermore, carotene injected in oil appeared to be as effective as colloidal carotene. The presence of 5 per cent of glucose in the suspension of colloidal carotene failed to affect the results in any way.

TABLE I
EFFECT OF CAROTENE ADMINISTERED IN VARIOUS WAYS

LEVEL OF CAROTENE GIVEN ($\mu\text{g}/\text{WK.}$)	MEDIUM	METHOD OF ADMINISTRATION	AVERAGE GAIN IN WEIGHT AT 5 WK. (Gm.)	AVERAGE CAROTENE IN LIVER AT DEATH (μg)	AVERAGE CAROTENE AT SITE OF INJECTION (μg)
1,500	Water	(a) Parenteral* Intraperitoneal	62	365 (211 to 507)	1,807 (1,605 to 1,990)
1,500	Water	Subcutaneous	63	106 (14 to 153)	1,860 (1,560 to 2,220)†
750	Water	Intraperitoneal	57	185 (112 to 246)	750 (585 to 1,030)
750	Water	Subcutaneous	62	129 (118 to 141)	543 (480 to 600)
750	Water (glucose)	Intraperitoneal	69	184 (126 to 274)	619 (576 to 658)
750	Oil	Intraperitoneal	67	45 (21 to 87)	1,766 (1,185 to 2,140)
375	Water	Intraperitoneal	37	44 (6 to 90)	40 (15 to 75)
75	Water	Intraperitoneal	All dead	5 (trace to 15)	4 (2 to 8)
75	Oil	Intraperitoneal	All dead	8 (trace to 11)	153 (115 to 229)
750	Water	(b) Oral	91	—	—
75	Water	Stomach tube	58	—	—
7	Oil	Dropper	60	—	—

*At least 3 animals were used at each level.

†Some carotene was also found in the mesentery and omentum.

The potency of colloidal carotene given orally was demonstrated not only by the amount of growth elicited, but also by the fact that 750 μg given each week for five weeks resulted in the hepatic storage of 567 blue units of vitamin A. By way of contrast the injection of 1,500 μg of colloidal carotene failed to yield any stores of vitamin A. Carotene injected in oil likewise failed to produce stores of vitamin A.

Injected carotene, however, accumulated in large amounts in tissues other than the liver. Both the amount and the location of these deposits depended upon the method of administration. After intraperitoneal injection, carotene was found in the omentum, mesentery, lymph nodes, and in the abdominal fat and

membranes surrounding the liver. After subcutaneous injection, carotene was found in similar areas and also at the site of injection (Table I). Oil solutions of carotene given intraperitoneally remained in the abdominal cavity for a considerable period of time, and much less carotene migrated to the liver than after the injection of the colloidal preparation (Table I). Apparently carotene was treated in part as a foreign substance because young rats injected with India ink showed a distribution of carbon particles similar to that of carotene. The presence of carotene at the site of injection has been reported previously (van den Bergh, Muller, and Broekmeyer;³¹ Rydholm;⁵ Rea and Drummond;²¹ Wilson, Ahmad, and Majumdar¹²).

TABLE II

AVAILABILITY OF CAROTENE DEPOSITS FORMED BY PARENTERAL ADMINISTRATION

TOTAL CAROTENE GIVEN (μ g)	MEDIA	METHOD OF ADMINISTRATION	DAYS TO REAPPEAR-ANCE OF OPHTHALMIA	DAYS TO MAXIMUM INCREASE IN WEIGHT	DAYS OF SURVIVAL
1,250 (in 5 days)	Water	<i>Parenteral*</i> Intraperitoneal	30 (25 to 31)	22 (16 to 34)	39† (28 to 63)
1,250 (in 5 days)	Water	Subcutaneous	25 (21 to 30)	21 (13 to 31)	37† (28 to 54)
1,250 (in 5 days)	Oil	Intraperitoneal	36‡ (34 to 38)	38 (25 to 51)	39 (20 to 58)
250	Water	Intraperitoneal	16§	11 (9 to 13)	16 (5 to 26)
1,250 (in 5 days)	Water	<i>Oral</i> Stomach tube	71 (61 to 81)	50 (36 to 58)	90 (54 to 110)
50 (in 5 days)	Oil	Dropper	26 (21 to 29)	21 (11 to 29)	30 (24 to 36)

75 γ of carotene per week	Water	<i>Oral</i> Stomach tube	29 (24 to 34)	13	45 (26 to 64)

*At least 4 rats were used at each level.

†Some rats were killed when losing weight and showing severe ophthalmia, others died.

‡Two rats died without relapse of symptoms.

§Two rats showed no remission of ophthalmia; another died without relapse of symptoms.

||One rat died without relapse of symptoms.

(b) *Availability of Carotene Deposits.*—The presence of large deposits of injected carotene raised the question of their availability. Accordingly, rats were given large injections of carotene and were then continued on the basal ration with observations on growth, cure of ophthalmia, reappearance of ophthalmia, and time of death. Details of dosage, mode of administration, and results are given in Table II. The liver and various other tissues were analyzed for carotene.

Animals that were given 5 injections totaling 1,250 μ g of carotene grew for a short time, and their ophthalmia disappeared (Table II), but within a month ophthalmia reappeared with loss of weight until death supervened. In

all cases unutilized carotene was found in the livers and at the site of injection (Table III). Animals injected with only 250 μg of carotene were variable in therapeutic response, but deposits of carotene were invariably found at death. No essential difference in result was obtained when carotene was injected in oil solution or in colloidal suspension.

TABLE III
CAROTENE FOUND IN RATS AFTER INJECTION OF 1,250 GAMMA OF CAROTENE OVER A FIVE-DAY PERIOD*

METHOD OF ADMINISTRATION	MEDIA	TIME AFTER LAST INJECTION (DAYS)	TOTAL CAROTENE IN LIVER (μg)	CAROTENE AT SITE OF INJECTION (μg)

Subcutaneous	Water	30 \pm †	(8 to 15) 4 (traces to 18)	(127 to 151) 30 (4 to 182)
Intraperitoneal	Oil	30 \pm †	16 (traces to 42)	267 (138 to 352)

*Each value is an average of 3 or more rats.
†Animals had died of vitamin A deficiency.

To determine whether large deposits of injected carotene were more effective biologically than small deposits, we used animals which had been injected with 375 or 750 μg of carotene weekly for five weeks. Carotene deposits averaged 935 μg in the latter (Table I) as compared with 182 μg in animals injected only over the five-day period (Table III). Nevertheless, the behavior of the two groups of animals was essentially the same when they were continued on the basal low vitamin A diet. The restoration of growth and the cure of ophthalmia were temporary, and death occurred in an average of thirty-three days in both groups. Apparently the accumulated carotene was practically unavailable. No carotene was found in the urine or feces after its injection.

PARENTERAL ADMINISTRATION OF VITAMIN A

In view of the inefficient utilization of injected carotene, parallel experiments were performed with vitamin A.

(a) *Physiologic Requirements.*—Vitamin A was injected as an aqueous colloidal suspension or as a solution of halibut-liver oil in cottonseed oil. Seven hundred and fifty blue units injected weekly or fed by stomach tube restored growth, cured ophthalmia, and produced hepatic stores (Table IV). The results were essentially the same whether the colloidal vitamin was injected subcutaneously or intraperitoneally, or fed by stomach tube. When the vitamin was injected in oil solution, however, somewhat better growth resulted than when the colloidal vitamin was injected.

A general consideration of all the results obtained indicated that the efficiency of injected vitamin A was approximately equal to that of vitamin A given orally, as judged by the criteria of growth, cure of ophthalmia, and hepatic storage. At lower levels of administration, 30 and 75 blue units per week, the

biological response depended to some extent on the vehicle in which the vitamin was administered and also on the method of administration. Aqueous colloidal vitamin A was more effective when injected than when given orally (Table IV); oil solutions, on the contrary, were more effective when given by mouth.

TABLE IV
EFFECT OF VITAMIN A ADMINISTERED IN VARIOUS WAYS

LEVEL OF VITAMIN A GIVEN (B.U./WK.)*	MEDIA	METHOD OF ADMINISTRATION	AVERAGE GAIN IN WEIGHT AT 5 WEEKS (GM.)	AVERAGE HEPATIC STORES (B.U.)
750	Water	(a) Parenteral† Intraperitoneal	59	386
750	Water	Subcutaneous	70	358
750	Oil	Intraperitoneal	115	196‡
75	Water	Intraperitoneal	52	0
30	Water	Intraperitoneal	21 (1 dead)	0
30	Oil	Intraperitoneal	14 (2 dead)	0

75	Water	Stomach tube	-12 (2 dead)	0
30	Water	Stomach tube	-10 (2 dead)	0
30	Oil	Dropper	63	0

B.U. = Blue unit.

*The vitamin A was administered three times weekly for a five-week period.

†Each value is an average of 4 or more rats.

‡Some vitamin A and oil from the abdominal cavity were unavoidably included.

§One rat responded poorly throughout the experimental period.

The foregoing results may be rationalized on two assumptions: first, that colloidal vitamin A is relatively unstable to the acids of the digestive tract; and secondly, that the vitamin is more readily mobilized from the injected aqueous suspension than from an injected oil solution. The colloidal vitamin A was presumably present as the alcohol as a result of previously saponifying the halibut-liver oil, which contains the vitamin in the form of esters (Hickman^{32, 33}). This fact may be noteworthy because vitamin A alcohol and ester are reported to have unequal biological activities when given by mouth (Moll and Reid³⁴). It is of interest that Gordon and Titherington⁶ observed that vitamin A was somewhat more effective on parenteral administration than when given orally, whereas Greaves and Schmidt¹⁰ reached the opposite conclusion.

In contrast with carotene, most of the injected vitamin A accumulated in the liver rather than at the site of injection. For example, when 750 blue units of colloidal vitamin A were injected intraperitoneally and weekly for five weeks, 105 to 140 units remained in the peritoneal cavity, and 386 units appeared in the liver. On subcutaneous injection 20 blue units remained at the site of injection, and 358 units appeared in the liver. Injected oil solutions, however, persisted at the site of injection or in the abdominal cavity. Lipoidal masses containing 1,125 to 1,797 blue units were found adhering to the liver, although the liver tissue contained relatively little (Table IV).

(b) *Availability of Vitamin A Deposits.*—The question remained whether stores of vitamin A produced by injection could be utilized readily, or whether, like injected carotene, they were inert. Deficient rats, therefore, were given large injections of vitamin A and then continued on the basal diet. Notations were made on the reappearance of ophthalmia and the time of survival (Table V).

Two hundred and fifty blue units of colloidal vitamin A administered in one dose were insufficient to produce hepatic stores, although ophthalmia was cured and growth was promoted for a short time; following this, ophthalmia reappeared, growth failed, and death resulted. The response was essentially the same whether the colloid was given subcutaneously, intraperitoneally, or orally. However, a better response was obtained with injections in oil (Table V). A total of 1,250 blue units of colloidal vitamin produced the following hepatic stores over a five-day period: 142 blue units after intraperitoneal injection, 121 units after subcutaneous injection, and 149 units when fed by stomach tube.

TABLE V
AVAILABILITY OF VITAMIN A STORES OF RATS*

TOTAL VITAMIN A GIVEN (B.U.)	MEDIA	METHOD OF ADMINISTRATION	AVERAGE DAYS TO REAPPEARANCE OF OPHTHALMIA	SURVIVAL PERIOD (DAYS)
1,250 (in 5 days)	Water	(a) Parenteral		
1,250 (in 5 days)	Water	Intraperitoneal	79† (76 to 81)	88 (63 to 108)
250 (1 injection)	Water	Subcutaneous	64 (44 to 93)	87 (71 to 113)
250 (1 injection)	Water	Intraperitoneal	27 (13 to 46)	38 (13 to 75)
250 (1 injection)	Water	Subcutaneous	37‡ (32 to 40)	39 (15 to 69)
250 (1 injection)	Oil	Intraperitoneal	49† (31 to 63)	62 (39 to 88)
1,250 (5 doses)	Water	(b) Oral		
250 (1 dose)	Water	Stomach tube	53† (47 to 60)	71 (58 to 79)
		Stomach tube	24§ (13 to 40)	36 (18 to 62)

*Each value is an average of 4 or more rats.

†One animal died without relapse of symptoms.

‡Two animals died without relapse of symptoms.

§One animal showed no remission of ophthalmia.

Despite the similarity in the stores produced, the vitamin appeared to be more effective physiologically when injected than when given orally; injected animals lived for eighty-eight days as compared with seventy-one days for those given the vitamin orally (Table V). Ophthalmia was deferred for seventy-two days in the injected animals as compared with fifty-three for the latter. At death no stores of vitamin A were found either in the liver or at the site of injection. Vitamin A administered parenterally, therefore, was apparently utilized at least as efficiently as when given orally.

SUMMARY

Rats deficient in vitamin A were injected intraperitoneally or subcutaneously with carotene in aqueous colloidal suspensions or in oil solution. Growth was restored and symptoms of ophthalmia were cured, but the amount needed was ten to one hundred times as great, and the effect was less prolonged than when carotene was given orally. Parenteral carotene failed to yield stores of hepatic vitamin A even when 1.5 mg. were injected weekly for five weeks. Particles of injected carotene were found at the sites of injection, and also in the liver, omentum, and lymph nodes in the peritoneal cavity. Carotene in these areas was only partially available to the animal, since deficiency symptoms and death occurred while considerable amounts of carotene were still in evidence.

Much of the injected carotene could not be traced; it was not converted into vitamin A nor was it found in the excreta.

Vitamin A, in contrast to carotene, was utilized about as effectively when injected as when given orally. Aqueous colloidal preparations were utilized best when injected; oil solutions were utilized best when given orally.

We wish to express our appreciation to Lever Brothers Company whose financial support made this work possible.

THE INFLUENCE OF A PAROTID EXTRACT ON THE BLOOD SUGAR AND STRUCTURE OF THE PANCREAS OF THE RAT*

WILLIAM B. BIRNKRANT, M.S., M.D., NEW YORK, N. Y.

ASSISTED BY REBECCA SHAPIRO, M.S.

THE role of the parotid gland in carbohydrate metabolism has been the subject of controversy. Blood sugar-raising substances have been obtained from the parotid gland by Hiki and co-workers.¹ Takaes,² however, reported hypoglycemias following the injection of ether and alcohol extracts of this gland. Birnkrant³ demonstrated marked hypoglycemias in rats following total bilateral parotidectomies. Cahane and Cahane⁴ described hypertrophy and hyperplasia of the islands of Langerhans following bilateral parotidectomies on two dogs. Aunap,⁵ Dobrzaniecki, and Michalowski,⁶ reported diminution of hyperglycemias following parotidectomies in depancreatized dogs. Zibordi⁷ and Scollo⁸ have also demonstrated a relationship between the pancreas and the parotid gland in their experimental animal work.

There also has been some clinical evidence to support a parotid-pancreas relationship. Of Flaum's⁹ 27 patients with bilateral hypertrophy of the parotid gland, 16 had frank diabetes and 11 had incipient diabetes. He considers every patient presenting noninflammatory enlargements of the parotid gland a diabetic unless proved otherwise. Kenawy¹⁰ found approximately 2 per cent of the poorer agriculture classes in Egypt suffering from a chronic, painless, noninfectious, noninflammatory enlargement of the parotid gland. Ten per cent of the cases he studied were diabetics. All presented bilateral swellings.

Both Ferretti¹¹ and Dobreff¹² stated that hypertrophy of the parotid glands is a result of a compensatory mechanism, i.e., the parotid glands take on the function of the pancreas in some instances of hypoinsulinism. On the other hand, the Cahanes, and Dobrzaniecki and Michalowski interpreted their findings on the basis of an anti-insulin parotid hormone.

Although the work of these authors indicates a carbohydrate-regulating mechanism related to the parotid gland, apparently conflicting reports and opposing interpretations have made difficult a proper evaluation of this mechanism.

The present study was, therefore, undertaken to determine the effects of parotid extracts on tissues and on blood sugar levels. Blood-sugar raising sub-

*From the Laboratories of the Delamar Institute of Public Health, Columbia University.

stances have been prepared from the urine of diabetic patients by Werch and Altshuler,¹³ and by Harrow and associates.¹⁴ In order to determine whether a relationship exists between these blood-sugar raising substances isolated from the urine of diabetic patients and the parotid extracts used by the earlier workers, a parotid extract was prepared by modifying the method of Harrow and others in order to make it suitable for tissue work.

EXPERIMENTAL TECHNIQUES

(A) *Preparation of Extract.*—To 1,250 Gm. of fresh ground beeves' parotid gland from which the fat and fascia had been removed, 2,250 c.c. of distilled water were added. The mixture was digested for twelve hours at 10° C. in three-eighths its volume of 0.2 N sodium hydroxide, then filtered and centrifuged. The supernatant fluid was acidified to pH 5 with glacial acetic acid. Sixty cubic centimeters of 95 per cent alcohol, containing 30 Gm. of benzoic acid, were added for each liter of solution. The precipitate was sucked dry on a Buchner funnel, washed with alcohol and ether, dried in vacuo and weighed (precipitate I, weight 132 Gm.).

The crude extract was triturated with 12 c.c. of distilled water per gram and dialyzed at 4° to 10° C. for three days. The contents of the dialyzing membrane were evaporated in vacuo to a small volume and centrifuged. The dried sediment (precipitate II) weighed 104 Gm.

To the supernatant fluid from this centrifuged mixture, absolute alcohol was added to make a final 95 per cent solution. This solution was kept at 4° to 10° C. for thirty-six hours and then centrifuged. The sediment was washed with alcohol and ether and dried (precipitate III, weight 320 mg.). Precipitate III was composed of thin, highly refractile, monoclinic, tetragonal crystals, soluble in water and dilute alcohol, insoluble in absolute alcohol and ether, and partially soluble in acetone. It turned brown and gummy on standing.

(B) *Blood Sugar Determinations.*—Precipitates I, II, and III were injected intraperitoneally into male Long-Evans hooded rats, eight to twelve weeks old and weighing from 207 to 305 Gm. The rats were kept on a well-balanced constant diet. Blood samples were secured from the palmar veins. The modified microcolorimetric method of Benedict¹⁵ was used for the sugar determinations. This method determines nonfermentable substances equivalent in reducing power to only 4 to 8 Gm. of glucose per 100 c.c. of blood.

For the glucose tolerance tests 1 Gm. of glucose per kilogram of rat weight was fed orally in a 50 per cent solution to the fasting rat. The rats were previously conditioned to medicine dropper feedings.

Six or more blood sugars were determined on each rat prior to the experimental procedures in order to establish normal means.

EXPERIMENTAL PROCEDURES AND RESULTS

(A) *Parotid Extracts.*—1. Precipitate I. Seventy-five milligrams of precipitate I were injected intraperitoneally into four fasting rats. Seven days later two of these rats were again injected with the same amount of extract, and fourteen days later one was reinjected. Fasting blood sugar levels were determined, and blood samples were secured in one hour, four hours, and twenty-four hours after injection.

In one hour the blood sugars showed an average increase of 87 per cent over the fasting blood sugars, ranging from 163 mg. per cent to 216 mg. per cent (Table I), representing a markedly significant rise (the sigma of the difference equals 12). Four hours after injection the blood sugars were still significantly higher than those of the fasting levels. In twenty-four hours all the blood sugars had returned to the preinjection range.

Mean per cent increase			61	26	27

2. Precipitate II. Fifty milligrams of precipitate II were injected intraperitoneally into each of ten rats daily for eight days. Samples of blood were secured on the eighth day immediately prior to the injection. Thereafter, one-hour, four-hour, and twelve-hour fasting samples were drawn from each rat. In one hour the blood sugars showed a 61 per cent average increase. The four-hour sample was 26 per cent above the mean blood sugars prior to the series of injections. Twelve hours after injection the same average increase was recorded (Table II). These average increases in blood sugars were statistically significant.

Eighteen glucose tolerance tests were done on 11 rats after they had received from one to twelve consecutive daily injections of 100 mg. of precipitate II (Table III). Fasting blood samples were secured immediately before injection. Fourteen rats were injected with 100 mg. of precipitate II just prior to the glucose tolerance test. Four rats were not injected immediately prior to the test, but received their last injection twenty-four hours previously. Two tests were done after one injection, two after three daily injections, eight after eight daily injections, four after nine daily injections, and two after twelve daily injections.

55	12	88± 5	119	0	241	155	137	126	146

In order to control the results eight glucose tolerance tests were done on rats not injected with the parotid extracts. Four of these tests were done after eight daily injections of physiologic saline, and two after eight daily beef extract broth injections. Two were not injected (Table IV).

The results of the control rats closely simulated glucose tolerance curves in normal human beings. Practically all the blood sugar curves following the use of precipitate II presented a picture similar to that in diabetic patients (Table III). The one-half-hour samples of the latter ranged from 148 mg. per cent to 585 mg. per cent, whereas the one-half-hour samples of the control animals ranged from 117 mg. per cent to 153 mg. per cent. The one-hour test samples of the rats injected with the parotid precipitate ranged from 155 mg. per cent to 270 mg. per cent, whereas that of the controls ranged from 101 mg. per cent to 128 mg. per cent. In the one-and-one-half-hour samples blood sugars ranging from 133 mg. per cent to 480 mg. per cent were obtained in the injected animals, in comparison to blood sugars ranging from 90 mg. per cent to 131 mg. per cent in the control animals. All the two-hour blood sugars of the control animals were normal, whereas the two-hour samples of the injected animals ranged

from 126 mg. per cent to 266 mg. per cent. The three-hour samples from the injected animals ranged from 101 mg. per cent to 272 mg. per cent (Tables III and IV).

Per cent increase over control rats			18		38	71	50	57	47

Three distinct types of curves were obtained. The most frequently encountered (Table V) reached its peak within one hour, with an average 71 per cent higher than that of the controls. The blood sugars of the control animals uniformly reached a peak in one-half hour. There was a 47 per cent increase in the three-hour samples over those of the controls. The average of the three-

hour blood sugars of the test animals was higher than that of their fasting blood sugars; whereas the average of the three-hour samples of the control rats was lower than the average of their fasting samples (Tables IV and V). All the average increases in the blood sugars of the test animals were statistically significant.

The second type of curve was encountered in Rats 3, 55, and 14 after eight daily injections, and in Rat 3 after nine daily injections. Extreme blood sugar rises from 304 to 585 mg. per cent were obtained in the one-half hour to the one and one-half hour samples (Table III). Sharp drops in the following samples followed these extreme peaks. Secondary peaks in the two- or three-hour blood samples were encountered in the tolerance test of six rats.

Although the majority of the tolerance curves paralleled the first type, the rats did not react constantly with any one specific type.

3. Precipitate III. Five milligrams of precipitate III were injected into seven rats. The mean of the blood sugars one hour after injection was 57 per cent higher than that of the mean of 42 blood sugars prior to the injections, representing a highly significant increase. The mean of the three-hour blood sugars was 25 per cent higher than that of the control sugars (Table VI).

Three glucose tolerance tests (Table VII) after injection of 3 mg. of precipitate III were similar to those obtained after the injection of 100 mg. of precipitate II.

(B) *Tissues*.—Two rats were autopsied after having received eight daily injections of beef extract broth. Seven rats were autopsied after nine to twelve daily injections of precipitate II, and in addition one injection of precipitate III.

The pancreas of the rats injected with beef extract broth presented no changes in the parenchyma of the islands of Langerhans.

The parenchyma of the pancreas of those rats which had received the injections of the several parotid extracts was normal. The majority of the islands of Langerhans were normal in size, shape, and arrangement of the island cells. In all the specimens, however, there were islands exhibiting marked granular degeneration, hydropic degeneration, disorganization of the normal island pattern, and varying degrees of infiltration with small round cells and fibroblasts. In several islands there was almost complete replacement of the island cells with young fibroblasts. Sections of the parotids, livers, spleens, kidneys, and thyroid glands of the extract injected animals revealed no pathologic changes.

DISCUSSION

The constant and prolonged hyperglycemias following intraperitoneal injections of the parotid extracts indicate the existence of an insulin antagonist secreted by the parotid gland. The markedly significant 84 per cent increase in the one-hour samples following the injection of precipitate I into seven fasting rats may possibly be explained by assuming that glycogenesis was being inhibited, whereas glycogenolysis was proceeding at a normal rate, thus resulting in an abnormal accumulation of endogenous glucose in the blood.

Injections of an average of only 5 mg. of precipitate III into seven rats produced an average increase of 57 per cent in the one-hour samples. Similar increases were obtained following the use of precipitate II in nine rats. Injections of 5 mg. of the refined crystalline precipitate III produced hyperglycemias comparable to those following 50 mg. of precipitates I and II (Tables I, II, and VI). We cannot, however, state that precipitate III was ten times as potent as precipitates I and II, since the end point of the inhibiting effects of the extract has not yet been determined. A chemical analysis of the crystals constituting precipitate III is still in progress.

The blood sugars of rats that received the parotid extract for the first time returned to the preinjection level within twenty-four hours, whereas the fasting blood sugars of those rats that received repeated daily injections were 31 per cent greater than their preinjection average.

These findings demonstrate that, although the inhibiting effect of the parotid substance disappears within twenty-four hours after one massive dose, repeated injections tend to maintain the fasting blood sugars at higher levels, even after the cessation of the injections due to the degenerative changes in the islands of Langerhans. This effect is exemplified by the glucose tolerance tests of Rats 15, 3, 14, and 55 (Table III), in which occurred peaks of 231, 480, 185, and 241 mg. per cent, twenty-four hours after the last injection of parotid extract. The normal glucose tolerance curves of control Rats 4 and 33, that had been repeatedly injected with beef extract broth, make improbable the possibility that a nonspecific irritating effect of intraperitoneal injections of a tissue extract may have resulted in hyperglycemia. Sections of the pancreas of these rats revealed no abnormal changes. Likewise, the normal glucose tolerance curves of the four rats which received repeated intraperitoneal injections of physiologic saline solution exclude the possibility that the hyperglycemias in the test animals were the result of repeated peritoneal punctures.

It is difficult in the present stage of this study to determine whether the degenerative changes in the islands of Langerhans following injections of the parotid extracts represent a reaction to a specific cell toxin, or are the end results of an accelerated type of atrophy of disuse following prolonged inhibition of all function.

Werch and Altshuler, and Harrow and co-workers, prepared blood-sugar raising substances from the urine of diabetic patients. The former found greater amounts of this substance in the urine of persons with diabetes than in the urine of normal individuals, and even greater amounts in urine in uncontrolled diabetes than in that of controlled diabetes. In the present study the method used by Harrow and associates to extract blood-sugar raising substances from the urine was applied in a modified form to the parotid gland. A potent blood-sugar raising extract was secured.

Himsworth¹⁶ in 1936 suspected the presence of an insulin antagonist. He suggested that diabetes mellitus in the insulin-sensitive person was due to a lack of insulin, whereas diabetes in the insulin-insensitive person was due to an insulin antagonist. It is possible that his two types of patients with diabetes represent two different stages of a condition with the same etiologic mechanism. An island of Langerhans antagonist may cause primary effects through its specific insulin antagonism and secondary effects following permanent damage to the islands of Langerhans. This damage may be due to either an atrophy of disuse, or a specific cell toxin.

SUMMARY

1. A potent blood-sugar raising extract was prepared from the parotid gland.
2. Degenerative changes in the islands of Langerhans followed repeated injections of this extract in experimental animals.

14 FIFTH AVENUE

THE ORAL ASCORBIC ACID TOLERANCE TEST AND ITS APPLICATION TO SENILE AND SCHIZOPHRENIC PATIENTS*

ELMER STOTZ, PH.D., BURTON M. SHINNERS, M.D., AND
RUPERT A. CHITTICK, M.D., BOSTON, MASS.

IT IS well known that there is a wide difference in the amount of ascorbic acid intake necessary to prevent the outward manifestation of scurvy and the amount desirable for optimal health.¹ As evidence accumulates concerning the true physiologic functions of vitamin C, such as the work of Sigal and King² on vitamin C levels and resistance to bacterial toxins, and of Ecker and co-workers³ on the relation between ascorbic acid and guinea pig complement, there will be an increasing need of a simple clinical procedure for determining the status of vitamin C nutrition in patients. The many techniques already available are well reviewed by authorities in this field in *The Vitamins*, edited in 1939 by the American Medical Association. Determination of the "resting level" of excretion⁴⁻⁶ and of "saturation deficits"^{7, 8} involve so many difficulties

*From the Biochemical Laboratory of the McLean Hospital, Waverley, Mass., and the Department of Biological Chemistry, Harvard Medical School, Boston.
Received for publication, December 9, 1940.

of performance and interpretation, not the least of which is the long time necessary for the test, that these techniques have not found general adoption in the clinic.

The significance of the plasma ascorbic acid content in single fasting specimens has been considered by many⁹⁻¹² to be of very limited value as an index of vitamin C nutrition, a belief that is further confirmed by our work. The lack of agreement^{13, 14} concerning the clinical significance of such fasting values is itself evidence of the inadequacy of this otherwise simple test. Butler and Cushman¹⁵ have found that the white blood cells and platelets may retain most of their ascorbic acid content even when the plasma ascorbic acid has been reduced to zero, and are themselves reduced to low ascorbic acid values only in acute scurvy. These authors believe that ascorbic acid analyses of these cells "provide indices of vitamin C deficiency which extend beyond the limit of the index furnished by fasting plasma concentrations." Their data indicate, however, that the vitamin C content of these cells is nearly maximal at low plasma concentrations, so that while analysis of these cells may indicate the severity of an existing scurvy, it would not be as sensitive an index of less severe vitamin C unsaturation.

Since the basic interest in "saturation tests" is the existing vitamin C content of the tissues, and since this substance appears to be in the free state both in the tissues and plasma, a reliable index should be furnished by the rate of penetration of the vitamin from the plasma into the tissues. Thus upon feeding the vitamin, if the tissue ascorbic acid content were low, the rapid flow of ascorbic acid from the plasma to such tissues should result in only a small rise of the plasma ascorbic acid; if the tissues were "saturated," then the plasma content should increase markedly. These suppositions were found to be true. Such a tolerance curve with vitamin C administered both orally and intravenously has been used in conjunction with other "saturation tests" by Portnoy and Wilkinson¹¹ in a study of normal patients and those with ulcer. The test was not studied in detail by these authors, however, and no attempt was made to relate the various degrees of saturation with the type of tolerance curve obtained. Intravenous "test dose" methods with measurement of the urinary excretion have been suggested¹⁶⁻¹⁹ to eliminate possible errors due to differences in intestinal absorption rates. Intravenous administration must in our opinion, and in agreement with that of van Eekelen and Heinemann,²⁰ involve a sudden flooding of the kidney and loss of a large amount of ascorbic acid, so that the blood values and urinary excretions observed must be greatly influenced by the speed of injection and secretory ability of the kidney. In the "oral" test to be described, the dosage was so chosen that rarely more than 10 to 15 per cent of the total dose was excreted during the five-hour test. Hence the principal factor in determining differences in the curves appeared to be the fundamental one, namely, the rate of penetration of the vitamin from the plasma into the tissues. The shape of an individual curve is, of course, determined in large part by the rate of intestinal absorption, as is the case with a sugar tolerance curve, but in our series we have not encountered any cases in which this factor appeared to be the main determinant of differences in the shape of a group of oral tolerance curves. Proof of this fact lies chiefly in the satisfactory explanation of differ-

ences on the basis of vitamin C nutrition alone, and on those changes produced by experimental feeding and deprivation of the vitamin in a single individual, where the factor of gastrointestinal absorption must be considered to remain constant. If cases of exceptionally slow absorption were encountered employing this test, the curve would at least suggest deficiency and lead to vitamin C therapy, and if this failed to produce a "saturated" type of curve, other methods of administration for therapy would be indicated.

This paper includes a study of (a) the use of the oral ascorbic acid tolerance test for a rapid clinical diagnosis of the degree of subclinical vitamin C deficiency; (b) the changes produced in the curve upon experimentally saturating and depleting the same individual of vitamin C; (c) the analysis of sufficient tolerance curves to distinguish at least four "types" characteristic of various degrees of vitamin C nutrition; and (d) the application of the method to a study of schizophrenic and senile patients.

METHOD

The test is best performed in the morning. A sample of blood (approximately 7 c.c.) from a fasting patient is taken with a dry syringe and ejected into a dry pyrex tube containing approximately 20 mg. of potassium oxalate as an anticoagulant. Mixing is accomplished by gentle inversions rather than by vigorous shaking to avoid hemolysis. A dose of 6.0 mg. of ascorbic acid per kilogram of body weight is dissolved (immediately before feeding) in one-half glass water and fed, the time in minutes being noted. Since no food should be given for the following five hours, we have allowed, after the vitamin C, a breakfast consisting of a cup of coffee and plain toast. This did not materially affect the resultant curve, but made the test more tolerable to the patient. Although in our experimental work we have taken five more specimens of blood to determine the details of the curve, sufficient information for clinical tests may be obtained by taking blood specimens at only the two-and-one-half- and five-hour points. The blood samples should be chilled immediately after drawing until they are analyzed (the same day). The chemical determinations of plasma ascorbic acid were done by a method developed in this laboratory²¹ which proved to be a rapid clinical method for serial analysis. It is a modification of the Mindlin and Butler procedure,²² with extraction of the unchanged 2,6 dichlorophenolindophenol into xylene, which insures its stability.

The values obtained in milligrams per cent are plotted against time in minutes.

INTERPRETATION OF CURVES

For the sake of clarity of presentation and economy of space it would seem better to present first a chart summarizing the types of curves which have been distinguished in our group of 60 such determinations, and to discuss the bulk of our data by reference to such a chart. Special illustrative curves will be presented after the generalized data. Fig. 1 shows a "mapping out" of convenient areas (outlined by dark lines) into which nearly all individual curves can be allocated.

These areas have been designated tentatively by the terms "saturated," "low normal," "high normal," and "undersaturated," but the distribution of subjects within these groups must vary somewhat according to location and

dietary habits. In view of such experiments as that reported by Crandon and Lund,²³ in which the plasma ascorbic acid was reduced (experimentally) to zero without clinical signs of scurvy or other pathology, it is in fact difficult at the present time to define sufficiency and deficiency with respect to vitamin C. Since in clinical scurvy the plasma ascorbic acid may not reach the zero level,¹⁴ the clinical syndrome probably also depends on the intake of other dietary factors, and it becomes desirable to be able to detect milder degrees of ascorbic acid deficiency.

Fig. 1.—Areas chosen to classify types of tolerance curves obtained.

In Fig. 1 it may be noted that there is a small area common to both Areas II and III. This will be discussed later, but it signifies that in spite of a fasting value as low as 0.4 mg. per cent, further characteristics of the curve may, nevertheless, indicate that it should be placed in Area II.

Fig. 2 illustrates some typical curves obtained and their proper allocation in the defined areas which are in this figure represented by dotted lines.

Type I curves, as illustrated, are the type given by "saturated" patients. This type has been encountered only twice among our group of patients, but can be produced at will by feeding extra vitamin C, e.g., 200 to 300 mg. per day for two weeks. In 15 persons possessing among themselves all the other types of curves, we have, by feeding ascorbic acid, converted them into "saturated" persons possessing the type I curve. A typical curve is characterized by a high initial ascorbic acid value, a moderate rise, and generally a failure to decline again in the experimental period. The failure to rise to higher levels is considered to be due to exceeding the kidney threshold (assumed by many²⁴ to be approximately 1.4 mg. per cent) so that the rate of excretion is equal to or exceeds the rate of intestinal absorption. Thus subjects showing this type of

curve usually excrete in the urine large proportions (60 to 100 mg.) of the test dose. In addition, "saturation" of the tissues prevents these tissues from absorbing any considerable amount of plasma ascorbic acid.

Fig. 2.—Illustrative oral ascorbic acid tolerance curves.

Type II curves, as illustrated in Fig. 2, were found in testing 13 normal nurses (male and female) and 20 hospital patients. All of these had normal dietary habits, being on the regular hospital diet. This group displays many variations in the tolerance curve, but all are characterized by marked rises and various rates of fall. The rise signifies that the rate of intestinal absorption exceeds the rate at which the relatively saturated tissues can absorb ascorbic acid from the plasma, the latter rate displaying itself only after intestinal absorption is more or less complete (latter part of curves). Although urinary excretion (from 15 to 50 mg. during the five hours) parallels the height of the curve in many instances, there were several cases of abnormally higher or lower excretions than that predicted from the curves.

Several persons possessing type II curves could not have been distinguished from patients possessing curves in the next lower state of saturation on the basis of fasting values alone (see type II-b). Thus in our group of 33 type II curves there were 9 subjects whose fasting values fell between 0.35 and 0.7 mg. per cent but who could not be considered from the tolerance curves to be any less "saturated" than those possessing higher fasting values.

Type III curves have been found in four patients of our series and in two other persons during a period of experimental deprivation of vitamin C. The type is characterized by relatively low fasting values (0.35 to 0.7 mg. per cent), with only slight or very transitory rises in the tolerance curve. It is included

as a category, since it is probable that this intermediate type represents a relative unsaturation and will occur quite frequently in the general clinic where patients of more varied dietary habits are encountered.

Fig. 3.—Experimental changes produced in tolerance curves of patient N by feeding and deprivation of vitamin C.

Type IV, illustrated in Fig. 2, is typical of vitamin C deficiency. Five of our group, all senile patients, have shown such curves and will be discussed in more detail later. In five experimental persons placed on a vitamin C deficient diet, we have likewise obtained such curves. In such cases the flow of ascorbic acid from the plasma to the unsaturated tissues apparently always exceeds the rate of intestinal absorption. Urinary excretion during the period never exceeds 2 to 3 mg. in these cases. Such curves may not be uncommon in the general population and certainly represent a state of unsaturation requiring vitamin C therapy.

EXPERIMENTAL CHANGES IN THE TOLERANCE CURVE

In order to demonstrate experimentally the variations in the tolerance curve of the same patient on different vitamin C intakes, the tolerance curves of three persons (schizophrenic) were determined on the regular house diet after two weeks of daily administration of 200 mg. vitamin C, followed by seven weeks on a vitamin C deficient diet. Two more patients were placed on the deficient diet. As illustrative of the data obtained, the tolerance curves of one of the first group are shown in Fig. 3, the other data are recorded in Table I. In each case we were able, by feeding ascorbic acid, to produce a tolerance curve, indicating greater saturation, and by deprivation to produce an "unsaturated"

type of curve. Since none of these patients or any others showing type IV curves ever showed any signs of clinical scurvy, the oral tolerance test described here is obviously to distinguish relative degrees of saturation or to differentiate between sufficiency and mild deficiencies.

Fig. 4.—Oral tolerance curves on senile patients, before and after supplementary vitamin C feeding.

VITAMIN C AND SENILITY

Other workers²⁵⁻²⁷ have given evidence to indicate a vitamin C lack in senility. Although Berkenau²⁷ has seemed to establish that these findings indicate a true hypovitaminosis C, since such patients required a longer time to "saturate," it was of interest to study such patients with our technique. We have, therefore, carried out the oral ascorbic acid tolerance test on a group of six senile persons. All showed the "unsaturated" or "low normal" (type IV or III) curves. Upon feeding 300 mg. of ascorbic acid per day for two weeks, they showed tolerance curves of type II or I, i.e., curves typical of greater saturation. One example of this is shown in Fig. 4, and the rest of the data are shown in Table II. These patients had been in the hospital on an adequate intake of vitamin C so that the deficiencies indicated by the initial tolerance curves could not be justified on the basis of dietary habits.

No satisfactory explanation (based on experimental proof) of this "endogenous" deficiency of vitamin C in senility has yet been offered.^{27, 28} Our data indicate that the fault does not concern intestinal absorption, since such patients display typical saturation curves after feeding of supplementary vitamin C. The basis of this deficiency is under investigation. In the meantime it seems established that better degrees of saturation can be and should

be maintained in senile patients by oral administration of extra ascorbic acid. That this deficiency may be associated with the pathology of senility rather than with "old age" as such is indicated by the finding that 14 other hospital patients from ages 65 to 90 years showed fasting plasma values over 0.7 mg. per cent.

TABLE I

EXPERIMENTAL CHANGES PRODUCED IN TOLERANCE CURVES BY FEEDING AND DEPRIVATION OF ASCORBIC ACID

In our group of 20 schizophrenic patients there have been no indications of vitamin C deficiency.

SUMMARY

An oral ascorbic acid tolerance test has been developed to indicate the relative saturation of vitamin C in human beings. On the basis of 60 such determinations, and on experimental changes produced in the curve upon supplementary feeding and deprivation of vitamin C, four categories of relative saturation have been suggested. Since patients showing the lowest "saturation" that can be demonstrated by this test do not show any signs of clinical scurvy, the test is obviously to detect lesser degrees of ascorbic acid deficiency. The main characteristics of the tolerance curves can be adequately distinguished by a fasting blood specimen and two other specimens in the following five hours. The use of this test seems to overcome the unreliability of a single fasting determination of plasma ascorbic acid, and to eliminate the technical difficulties of urine collection involved in previously suggested tests for the degree of vitamin C saturation.

Application of this test has demonstrated a vitamin C deficiency in senile patients which is not related to dietary habits, and has indicated no disturbance of vitamin C saturation in schizophrenia.

We wish to express our thanks to Doctors Kenneth J. Tillotson and W. Franklin Wood of McLean Hospital, and to Professor A. Baird Hastings of the Harvard Medical School, for their suggestions and criticism in this work.

THE EFFECT OF YEAST AND MUSCLE ADENYLIC ACID IN MALNOURISHED PERSONS WITH PELLAGRA AND PERIPHERAL NEURITIS*

RICHARD W. VILTER, M.D., WILLIAM B. BEAN, M.D., AND
TOM D. SPIES, M.D., CINCINNATI, OHIO

INTRODUCTION

YEAST and crude liver extracts are effective in the treatment of pellagra beriberi, and riboflavin deficiency because they are excellent sources of the vitamins of the B complex, particularly nicotinic acid, thiamin, and riboflavin. Many less well-known compounds are also present in high concentration and, like nicotinic acid, thiamin, and riboflavin, are components of organic catalysts essential for cell respiration. Adenylic acid is one of these compounds. It is the precursor of adenylyl pyrophosphate (cophosphorylase) and is a component of a number of polynucleotides, including the nucleic acids, the coenzymes I and II, the prosthetic groups of xanthine oxidase, d-amino acid oxidase, and the yellow enzyme. These considerations suggest a relation of adenylic acid and the vitamins of the B complex, and indicate its great theoretical importance to cellular respiration and nutrition.

In this study 29 selected patients with nutritional deficiency disease were given adenylic acid prepared either from yeast or from muscle.† The patients have been divided into four groups to facilitate description of the therapeutic results.

Group I. Sixteen pellagrins in relapse. This group consisted of 16 persons, all of whom in previous years had responded to nicotinic acid therapy for pellagra. They had continued to subsist on deficient diets, and in the spring of 1940 again had developed clinical evidence of acute pellagra in relapse. Six of this group had multiple ulcers, extending deep in the tongue or buccal mucous membranes. The fiery red borders of the ulcerations were swollen and sharply demarcated from the surrounding tissue. The craters of the ulcers were covered with grayish-white membranes. Each of these 6 patients complained of severe pain around the areas of ulceration and of generalized burning sensations of the entire mouth and tongue. The remaining 10 patients had no ulcerative lesions of the tongue or oral mucous membranes, but each had characteristic pellagrous glossitis and complained of burning sensations of the mouth and tongue; two of these 10 patients also had riboflavin deficiency, as evidenced by severe conjunc-

Received for publication, December 26, 1940.

†Yeast adenylic acid was furnished through the courtesy of Merck and Co., Inc., Rahway, N. J., the Fleischmann Laboratories, New York, N. Y., and Anheuser-Busch, Inc., St. Louis, Mo. Muscle adenylic acid was supplied by the Ernst Bischoff Company, Ivoryton, Conn.

tival and circumcorneal injection, and cheilosis. None of these lesions improved while the patients were restricted to their usual deficient diet for two weeks of preliminary observation. At the end of this period the administration of adenylic acid was begun. Each person was given intravenously 50 mg. of either yeast adenylic acid or muscle adenylic acid, dissolved in sterile physiologic solution of sodium chloride, twice daily for from one to three days. The solution was injected not faster than 2 mg. per minute. The 14 patients receiving yeast adenylic acid and the 2 receiving muscle adenylic acid reported improvement in strength, and then rapid disappearance of all burning sensations of the mucous membranes within six hours. The ulcerations in the mouths of 6 pellagrins healed within two to five days after the first administration of adenylic acid. Those patients who continued to eat an inadequate diet had recurrences of the ulcerations and a diminution of strength within three to five weeks. When relapse occurred, some of these patients requested more of the "same medicine," despite the discomfort that accompanied the injection. The fiery red color of pellagrous glossitis and the cheilosis and conjunctivitis of riboflavin deficiency were not affected by adenylic acid.

Group II. Four persons with prodromal symptoms of pellagra. Four persons, each of whom had been observed with clinical pellagra in previous years, had continued to eat an inadequate diet. When seen in the Nutrition Clinic this year, they complained of weakness, vague pains, irritability, insomnia, and burning sensations of the skin and mucous membranes. Three were given 50 mg. of yeast adenylic acid b.i.d. and one was given 50 mg. b.i.d. of muscle adenylic acid for from one to three days in the manner described.

Within six hours after the first injection these patients reported an increase in strength and vigor, and disappearance of all burning sensations of the skin and mucous membranes. The dramatic disappearance of anxiety, irritability, and nervousness, which follows the intravenous injection of large amounts of thiamin hydrochloride, was not observed after the injection of adenylic acid in the doses used. Accordingly, after this study a single dose of 100 mg. of thiamin hydrochloride was given intravenously and was followed by relief from these nervous symptoms within a few hours.

Group III. Six persons with peripheral neuritis which was refractory to treatment with thiamin hydrochloride and brewers' yeast. Six patients were selected because of severe refractory peripheral neuritis. Five of these persons were addicted to alcohol; the sixth had had recurrent attacks of pellagrous glossitis for ten years and peripheral neuritis for three years because of faulty gastrointestinal absorption. A number of observers had studied these patients clinically, and had treated the peripheral neuritis for from one to three years. The neuritis had failed to respond to intensive treatment with brewers' yeast for two months or more, or to the intravenous administration of from 50 to 100 mg. thiamin hydrochloride daily for a minimum of fourteen days. Before adenylic acid was administered, neurologic examination of each person showed the following similar abnormalities which had been observed before treatment with yeast and thiamin hydrochloride: Each had severe paresthesias of the feet and legs, both spontaneous and in response to pinprick and stroke, diminished perception of

light touch and vibration in the ankles and knees, and diminished appreciation of the position of the toes. Ankle jerks were absent and knee jerks were hypoactive in every case. Each of these patients received, intravenously, 25 mg. of yeast adenylic acid twice a day for ten to thirty days.

Spontaneous paresthesias temporarily disappeared during the administration of adenylic acid. In one case, for example, hyperesthesia, located at the knee before injection, was found near the ankle during the injection, but within fifteen minutes after the termination of the injection the level was found at the knee again. Similar responses were observed in each patient following each injection, but there was also a gradual and steady decrease in all painful sensations in the legs. Within ten to twenty-one days spontaneous pain and demonstrable hyperesthesia disappeared, perception of light touch improved, and the patients were able to walk without pain, whereas before treatment they could not bear the weight of bedclothes on their feet and legs. In 3 cases the knee jerks changed from hypoactive to active during the period of treatment, and the perception of vibration, previously absent in the knees, returned. Ankle jerks, the perception of vibration over the malleoli, and appreciation of the position of the toes, did not change during the period of observation.

Electrocardiographic tracings taken on these 6 persons, which were normal before injection, showed the following temporary changes during the injection: Tachycardia in 3 persons; P-R interval increases of more than 0.02 second in 4; Q-T interval increases of more than 0.02 second in 2; inverted cone-shaped T-waves in all leads in 1; inverted P-waves in Lead 3 in 1; flattened T-waves in all leads in 3. These alterations disappeared within five minutes after the cessation of the injection.

Group IV. Three persons with ulcerations of the tongue whose diets were adequate and who had no evidence of nutritional deficiency. Three persons were selected for comparison with the patients in group I because of recurrent superficial ulcerative lesions of the tongue for which no cause could be found. Their diets were adequate, they presented no evidence of nutritional deficiency disease, and the appearance of the ulcers bore no relationship to the season of the year. Each of these persons was injected intravenously with 50 mg. of yeast adenylic acid twice a day for from three to five days. At the time of injection there was no change in their sense of well-being and later no change in the appearance of the ulcers. They were given 500 mg. of nicotinic acid by mouth for one week. Still there was no healing in the ulceration or improvement in the burning sensations of the tongue in the regions of ulceration.

REACTIONS OBSERVED DURING THE INJECTION OF YEAST AND MUSCLE ADENYLIC ACID

Immediate reactions of varying degrees of severity, such as were described in normal persons,¹ were invariably observed with both the yeast and muscle adenylic acid preparations. Rapid injections of 5 to 10 mg. of either compound produced, within twenty seconds, a flushing of the face, deep inspiration, transient tachycardia, sensation of suffocation, and impending disaster; whereas slow injection of 2.0 mg. per minute produced mild hyperpnea, tachycardia, abdominal cramps, tingling sensations in the mouth, and mild apprehension.

Patients who had burning sensations in the abdomen and about the eyes and mouth stated that these sensations increased temporarily during the period of injection. Transient increase in lacerimation and injection of the conjunctival vessels were noted in several cases, particularly in patients who had conjunctival congestion. In contrast, the intravenous injection of adenine sulfate had no pharmacologic effect and no apparent physiologic effect.

These observations on the immediate reaction and the electrocardiographic alteration during the injection of adenylic acid support the previous observation of Honey, Ritchie, and Thomson,² Rothmann,³ and Ruskin and Katz,⁴ on the effect in human beings of intravenous and intramuscular injections of adenosine and ferrous adenyate, substances which act like adenylic acid in all particulars which we have studied.

SUMMARY AND CONCLUSIONS

1. These observations and those previously made suggest that the role of adenylic acid in human nutrition is important and extremely diversified. Within from two to five days following the daily intravenous administration of 50 mg. of adenylic acid from yeast or from muscle, the ulcers in the mouths of 6 malnourished persons disappeared. In contrast, the ulcerations in the mouths of 3 persons who had stomatitis, but no evidence of dietary deficiency, did not improve following the injection of similar amounts of adenylic acid. The administration of either yeast adenylic acid or muscle adenylic acid to persons with pellagrous glossitis or persons with subclinical symptoms of pellagra was followed by rapid improvement in strength and well-being and disappearance of the burning sensations of the mucous membranes.

2. The intravenous administration of yeast adenylic acid to 6 persons with peripheral neuritis who had failed to respond to brewers' yeast or to massive doses of thiamin hydrochloride, intravenously, was followed by striking clinical changes after a period of from ten days to three weeks. Spontaneous pain and demonstrable hyperesthesia disappeared, perception of light touch improved, and the patients were again able to walk without pain.

3. The intravenous administration of either muscle adenylic acid or yeast adenylic acid produced similar immediate reactions. Because of these reactions and the concomitant electrocardiographic changes, we do not recommend adenylic acid for general therapeutic use. Nicotinic acid and thiamin hydrochloride, given in conjunction with a diet rich in protein and calories, continue to be the most efficient therapeutic measures for most malnourished persons with ulcerative stomatitis and peripheral neuritis.

LABORATORY METHODS

GENERAL

FLUORESCENT STAINING TECHNIQUE FOR DETECTION OF ACID-FAST BACILLI*

HOWARD E. LIND, M.Sc., C.P.H., AND HOWARD J. SHAUGHNESSY, Ph.D.
CHICAGO, ILL.

ACID-FAST staining by the Ziehl-Neelsen method is a classic procedure. There are very few laboratories, either private, institutional, municipal, or state, that do not use this method. In view of the difficulties encountered with the Ziehl-Neelsen method, the introduction of a cold stain, followed simply by a decolorizing solution, is appealing in itself. Such is the procedure of the fluorescent technique.

The remarkable simplicity of the technique and the excellent results reported by Richards and Miller of New York prompted us in the Chicago Branch Laboratory of the Illinois State Health Department to apply it to use in a busy routine diagnostic laboratory under normal conditions.

A demonstration by Dr. Edmund Kline at the American Public Health Association Meeting in Detroit in October, 1940, was indeed convincing. It was not until January that we were able to experiment with this technique on a large scale, at which time accessory equipment was made available to us through the courtesy of the Spencer Lens Company.

The application of fluorescence microscopy to acid-fast bacteria and the use of filament rather than arc lamps are due to two German physicians, Hagemann and Keller. The equipment at present makes the method available for use with any monocular microscope and may be used only with materials whose fluorescence will be excited by the available ultraviolet light and the fluorescence that will pass through a yellow filter to the eye.

During the process of investigation of this method with direct and concentrated specimens, the following claims were kept in mind: (1) An increase in positives. (2) Reduction in fatigue in spite of the use of a monocular microscope. (3) Absence of interfering fluorescing substances. (4) Low cost of initial and upkeep of accessory equipment. (5) Rapidity of the procedure. (6) Practicability in small and large laboratories, hospital, and health department. (7) No specific experience necessary. During the course of this paper I shall try to clarify these claims.

*From the Illinois State Health Department, Chicago.

Read at the Laboratory Technicians' Section of the Tri-State Hospital Assembly Meeting, May 9, 1941.

Received for publication, May 12, 1941.

The method and equipment were developed and tested by Dr. Oscar W. Richards, of the Spencer Lens Company Research Department, and were first applied at the Meyer Memorial Hospital in Buffalo by Dr. D. K. Miller. Eleven sputa in their first series of 100 were found positive with this method which were negative with Ziehl-Neelsen. The fluorescence technique on direct smears had greater sensitivity than on concentrations with Ziehl-Neelsen. Acid-fast bacilli found in a spinal fluid and pus were not demonstrated by Ziehl-Neelsen. They also mentioned that one-third less time is required for preparing and reading smears.

Let us take up the necessary accessory equipment and procedure of the technique. (1) A monocular microscope is necessary. The present source of ultraviolet light is limited so that it would be almost impossible to obtain satisfactory light through a double body tube of a binocular microscope. We understand that this limitation is being worked on by Dr. Richards.^{*} The draw tube on a monocular microscope may be substituted for the binocular draw tubes of a Spencer microscope. (2) The microscope should be equipped with an 8 mm. objective and a 20 \times ocular or 1.8 mm. objective and a 6 \times ocular. (3) A source of light which has low voltage and high amperage, such as a Universal microscope lamp of 6.5 volts and 2.75 amperes with clear bulb and transformer, is desirable. Universal lamps Nos. 351 and 353 are suitable because the high amperage and concentrated filament furnish sufficient ultraviolet radiation for use with the monocular microscope. Apparently the less intense low voltage lamps and even many of the larger conventional lamps are not satisfactory because either less ultraviolet light is produced or too much of it is absorbed by the lenses. (4) A blue ultraviolet transmitting filter placed in front of the light source is essential. (5) An aluminum-surfaced mirror sets in front of the microscope mirror. This is necessary, since a silver mirror absorbs the ultraviolet radiation instead of reflecting it. (6) Finally a yellow light filter is placed in the ocular of the microscope. This is a complementary filter necessary to see the acid-fast bacteria which fluoresce to appear yellow.

The staining solution is composed of 0.1 gm. of Auramine O (National Aniline Company), 3 c.c. of liquefied phenol, and 97 c.c. of distilled water. The decolorizing solution is composed of 100 c.c. of 70 per cent alcohol, 0.5 c.c. of concentrated hydrochloric acid, and 0.5 gm. of sodium chloride. There is no counterstain.

We know that certain microorganisms are called acid-fast bacteria because they retain the basic dye (whether it be fuchsin or auramine) in a phenol or carbolic acid solution after the remaining material on the slide is made void of color with acid alcohol. The acid-fast bacteria retain auramine, a fluorescent dye, after the surrounding material has been destained with acid alcohol. When they are lighted with ultraviolet radiation, this light is absorbed and reradiated as visible yellow light. Consequently, the bacteria appear as bright self-luminous bodies on a dark, almost black, background. This effect is obtained by the blue ultraviolet transmitting filter on or in front of the light source and a yellow filter in the eyepiece. This arrangement becomes black to the eye because the

^{*}Personal communication.

yellow filter absorbs the radiation passed by the blue filter. (Since silver absorbs ultraviolet radiation, an aluminized mirror is substituted.) The yellow light, emitted by the organisms, since auramine is retained, passes through the eye filter and appears yellow.

Smears are made as usual and fixed by heat, as in the Ziehl-Neelsen method. Auramine is applied for two minutes, washed, and decolorized with acid alcohol for two to four minutes, and then redecolorized in a fresh solution of acid alcohol for at least two minutes, again washed and dried; it is now ready for examination. For staining purposes Coplin jars or individual staining may be used. The latter method is to be preferred. Regardless of which method may be used, it is important to use a clean, fresh solution of acid alcohol as a final decolorizer to insure complete decolorization. There is no danger of over-decolorizing, but there is trouble when insufficiently decolorized.

The matter of focusing may cause a little difficulty at first, but if maximum light is obtained before examination is attempted, this difficulty will be minimized. Place the blue ultraviolet filter on the lamp in front of the light source and focus it onto the center of the mirror. Remove ocular and focus objective as near to the stage as possible; then by adjusting the mirror so that the maximum light shines through the body tube, the slide may easily be focused.

The procedure recommended by Dr. Richards follows that an objective of 8 mm. and a 20 \times ocular giving a magnification of 400 be used, thus allowing an area 20 times that of oil-immersion lens objective with 10 \times ocular used ordinarily with the Ziehl-Neelsen method.

The acid-fast bacilli appear as small bright yellow bacilli against a dark background. In a pure culture of tuberculosis absolutely nothing but the organisms appear, the background being nearly black. With smears, direct and concentrated, the degree of various other substances present in sputum fluorescing varies, depending upon the method used in concentrating and any other phase used in the process of preparing the sputum for examination.

EXPERIMENTAL

The method and the equipment recommended have been tested under conditions of a public health department laboratory in which nearly all specimens of sputum for the examination of tubercle bacilli are mailed to the laboratory. A few specimens submitted for pneumonia typing were included in this series as direct smears. The test run included 1,123 concentrated specimens and 98 direct smears with the fluorescence method and with the Ziehl-Neelsen technique. Sputum submitted to our laboratory arrives in cresol; it is autoclaved and then centrifuged. Smears made from the sediment are stained and examined for tubercle bacilli. In addition to the recommended use of the low objective and the high ocular lens various combinations, including the oil-immersion and low ocular, were tried.

RESULTS

As seen in Table I a total of 1,221 specimens of sputa were tested. Of these only 98 were examined by direct smear. Ninety-six were negative and two were positive by each method. The bulk of the specimens examined under con-

ditions of concentration with cresol, autoclaving, and centrifuging did not reveal such striking differences as did the comparisons reported by Doctors Richards and Miller. Of the 1,123 specimens examined above, 998 were negative and 106 were positive by both methods. However, there were twelve specimens positive by the fluorescence method which were negative by the Ziehl-Neelsen technique (a re-examination of one of these specimens by the Ziehl-Neelsen was found to be positive). Very interesting to us, but slightly disturbing, was the fact that in seven sputa positive results were obtained by the Ziehl-Neelsen technique but could not be demonstrated by fluorescence. (Two of these smears were very thin, two were bloody, and one was unsatisfactory. Two, however, were missed completely.)

Not included in the foregoing series were four smears of pus and one spinal fluid which were negative by both techniques.

TABLE I
SPTUM FOR TUBERCLE BACILLI

NO. OF SPUTA	FLUORESCENCE TECHNIQUE		ZIEHL-NEESEN TECHNIQUE	
	DIRECT	CONCENTRATED*	DIRECT	CONCENTRATED
96	Negative	Negative Negative Positive Positive	Negative	Negative Positive Positive Negative
2	Positive		Positive	
998

12‡				
1,221				

*Concentrated with cresol, followed by autoclaving and centrifuging.

†Two smears were very thin, two were very bloody, one smear proved to contain artifacts (acid fast), not tubercle bacilli.

‡One of these was found to be positive by Ziehl-Neelsen technique on re-examination.

NOTE: Not included in the above were 4 smears of pus and spinal fluid which were negative by both techniques.

DISCUSSION

According to Richards and Miller, "A bright yellow tuberculosis organism is more easily seen against a dark background than the usual red stained bacterium on a blue background." As an individual, I would be inclined to agree, but I do not believe that would be the consensus of opinion of the group here. Unless there has been some experience with the dark-field microscope or some other fluorescence technique, the transformation is not as rapid and as easy as it sounds. One problem encountered is that of a mental approach. One must change his or her concept of tubercle bacilli as they should appear. The recommended use of an 8 mm. objective and 20× ocular lens gives one a wider vision and an area twenty times as large but reduces the magnification of the organisms to less than one-half. This difficulty can be overcome with practice. We would recommend that the beginner in fluorescence technique use the oil-immersion objective and a low ocular 6× or 10× just as for other stained preparations of bacteria. This would permit the eye to become accustomed to change in color contrast, without making it necessary to adjust to changes in changing the shape, size, and form of the organisms. It is true that cedar oil will fluoresce so that the background is tan rather than almost black. Also the point of focusing area or working distance is very narrow. Using the low objective

and high ocular (8 mm. and 20 \times , a magnification of 400 times), one can concentrate attention on change in size and shape.

There may be claims of fatigue at first because of the dark-field and monocular scope, but if the slide is protected from the glare of surrounding light, this objection is eliminated.

The rapidity with which one can examine these slides is very striking. One-fourth to one-third the time is required with this method compared with the Ziehl-Neelsen method once the smears are made. It is true that each field covers twenty times the area of that under oil immersion and increases the speed of examination, although it is necessary to guard against the tendency to lessen the importance of adequate examination of specimen because of increased area covered.

To overcome the problem of occasional thin slides that reveal nothing and render the focusing of the field difficult, apply a spot of auramine stain on the corner of slides.

Associated fluorescence has been a decided problem and inconvenience during this experiment. The fact that cresol fluoresces and nearly all our sputa arrived in cresol reduced distinct contrast, and nearly all material in the smear fluoresced to a greater or lesser degree. This was partially overcome by increasing the time of decolorizing, using low magnification to find suspicious areas and confirming with the oil-immersion lens and 6 \times ocular. The fact that cedar oil fluoresces as a dull haze blotted out the definite outlines of associated interfering fluorescing substances, while the tubercle bacilli remained clear, bright, and definite.

There has been some work by Dr. Kline* to the effect that heating reduces the sensitivity of the fluorescence stain. This may help to explain why this series involving autoclaving did not reveal such a striking increase in the number of positives. An increase of even 1 per cent is important.

If only one microscope equipped for the fluorescent technique were available in a laboratory, only one person could look at the slides. On the other hand, several people in the laboratory could look at slides stained by Ziehl-Neelsen technique. It would appear that no time would be saved by the fluorescent method. However, this is only partially true, for by the fluorescence method one individual could look at the same number of slides that two, three, and even four, could observe by the Ziehl-Neelsen method. The accessories to this method do not render the monocular microscope unsatisfactory for routine bacteriologic examination of other smears and cultures. It becomes satisfactory for any staining use by simply changing to another ocular minus the yellow filter.

The accessories are reasonable in price. The blue ultraviolet filter, aluminized mirror, and yellow filter are available for \$10.00 from the Spencer Lens Company. A Universal light of low voltage and high amperage costs \$23.00.

Other chemicals that will fluoresce very little, or not at all, used in concentrating sputum and yet satisfactory for mailing purposes were investigated.

This investigation revealed that the fluorescent technique for acid-fast bacilli, where applied to sputum concentrated with cresol, was not more satis-

*Unpublished work.

factory than our modification of the Ziehl-Neelsen method. It appears that cresol fluoresces to the extent of interfering with the clear fluorescence of the acid-fast bacilli.

This disadvantage does not apply to direct smears. Our series of direct smear examinations was too small to comment upon intelligently.

SUMMARY AND CONCLUSIONS

A total of 1,221 specimens were examined for tubercle bacilli with the fluorescent and the Ziehl-Neelsen techniques. Of these, 1,123 were specimens concentrated by cresol, autoclaving, and centrifuging. The fluorescence technique for the examination of tubercle bacilli was more sensitive than the Ziehl-Neelsen staining method, increasing positives by 1 per cent, although the use of cresol in concentration produced fluorescence which interfered with the examination of the specimens. Because of the larger areas covered and the ease of examination, the time required to examine the smears was reduced by one-fourth to one-third.

The disadvantages of a monocular microscope, the high degree of miscellaneous fluorescence, and the possible fatigue were counteracted by the advantages of larger microscopic fields, simplicity of technique, rapidity of procedure, and increase in number of positives. The simplicity of the technique permits a larger number of specimens to be handled in a shorter period of time.

A QUICK, EASY METHOD OF PREPARING TISSUES FOR MICROSCOPIC EXAMINATION BY COMBINING THE TECHNIQUES OF NELSON AND TERRY*

WILLIAM M. WILSON, M.D., PORTLAND, ORE.

THE purpose of this paper is to report a quick, easy, and inexpensive method of fixing, embedding (blocking), cutting, and staining tissues for microscopic examination. The technique is simple and can be mastered by any office or laboratory assistant in a few hours. With the equipment at hand and a little experience the actual working time necessary for carrying out all technical procedures is less than ten minutes. The only time-consuming part of the method is that required for adequate hardening of the tissue block, but this demands no attention. Hardening sufficient for cutting sections occurs in from two to eight hours, depending on the temperature of the media. Cutting, staining, and mounting for immediate microscopic examination can be accomplished within a few minutes.

I claim no credit for the development of any item in this technique. In fact, the procedure described herein merely represents the manner in which I have conveniently utilized, with minor modifications, the following well-developed techniques—(1) The use of protein for embedding small tissues, developed by I. A. Nelson¹ in 1934. (2) A new principle in the microscopic examination of fresh unfixed tissues, developed by Benjamin T. Terry² and first reported in 1926. Terry^{3, 4} has since reported numerous improvements in technique.

EQUIPMENT

1. Egg albumen crystals, 4 ounces. Albumin crystals make much better blocks than does powdered egg albumen. Domestic egg albumen crystals are superior to imported preparations of the same. These can be purchased at any baker's or candy maker's supply house.†

2. A sheet of ordinary wrapping cellophane (not waterproof) or patapar parchment paper‡ for making embedding boxes. Either of these can be purchased at most department stores. Patapar is easier to handle and makes a more stable box.

3. A small dish, about the size of a one-ounce ointment jar, is satisfactory.

4. Terry's safety razor blade microtome. Directions for making this inexpensive, clever little apparatus have been published by Terry.⁴ In a forth-

*From the Department of Gynecological Pathology, University of Oregon Medical School. Received for publication, May 13, 1941.

†I obtained this material from Gray and Company, 1305 N. W. Davis Street, Portland, Ore.

‡Manufactured by the Patterson Parchment Paper Company, Bristol, Pa.

coming publication Terry will describe his safety razor blade "pocket" microtome. A sharp old-fashioned razor may be used for sectioning, but obviously it is less convenient.

5. Formalin, 40 per cent (neutral or slightly alkaline), 4 ounces.

6. A medicine dropper.

7. Fine-pointed thumb forceps.

8. Clean cover slips and a microconcavity slide or a special slide such as described by Terry.⁴

9. A small slice of silk sponge strapped to a glass slide with waterproof adhesive tape.

Fig. 1.—An easy method of constructing cubical boxes for embedding purposes. The wood block shown above measures $\frac{3}{4}$ inch in all diameters.

10. A fine-pointed camel's-hair brush or a small inexpensive atomizer for applying stain.

11. Neutralized polychrome methylene blue (Terry)* 0.5 Gm. Place this into a clean 2 ounce bottle and add 50 c.c. of distilled water.

12. A microscope with a good microscopic light. If reflected light is preferred, a 100 watt, frosted, Mazda electric light bulb, provided with a shade or a small photo flood bulb, is recommended.

TECHNIQUE

Fixing and Embedding.—Three grams of egg albumen crystals are dissolved in 10 c.c. of tap water. This quantity of emulsion is sufficient for one large-sized block, or two small ones. Complete solution of the crystals takes from forty-five to sixty minutes, unless the mixture is stirred frequently. This time-consuming factor can be obviated by making up reserve quantities of the emulsion which can be preserved at refrigeration temperatures for several weeks.

*This can be obtained from Benjamin T. Terry, 1001 N. Yakima Ave., Tacoma, Wash.

Containers for blocking are easily made by folding 2½ by 4 inch pieces of cellophane or patapar into the shape of cubical boxes (Fig. 1). The box is placed in a small dish, such as the one-ounce ointment jar. The emulsion of egg protein is poured into the box, and the tissue (fresh or fixed) is placed in the emulsion. A single piece of tissue, as large as one square centimeter or numerous small fragments of tissue, such as small bits of endometrium, can be embedded into a single block. The coagulant, 40 per cent formalin, is poured into the dish around the box. The level of the formalin should be slightly below the level of the emulsoid. By dialysis the formalin gradually permeates the emulsoid, fixing the tissue and coagulating the egg protein to form a solid block. Hardening sufficient for cutting requires from two to eight hours, depending on the temperature of the media. (After a little experience in palpating blocks, the degree of hardness sufficient for cutting is easily determined.)

Fig. 2.—Low-power view of an endometrial polyp.

In an incubator at 140° F. a sufficient hardening can be secured in about two hours, while at a temperature of 70° F. adequate hardening may take from eight to ten hours. The box containing the egg emulsion and tissue may, however, be left in the formalin for twenty-four hours or more without danger of excessive hardening. When sufficiently hardened, the block is held in running water for a few seconds to remove the excess formalin. The cellophane or patapar wrapper peels off easily. After trimming, the block is ready for cutting. When small fragments of tissue, such as strips of endometrium, are embedded, it is usually more convenient to divide the block into two or more squares before sectioning. If it is not convenient to cut sections immediately, the block should be immersed in water to prevent drying and cracking. Any portion of a block before or after cutting can be preserved in tap water for days, or in 5 per cent formalin for months. Tissue embedded by this method is easily re-

Fig. 3.—Medium-power view of endometrium secured by suction curettage. Chronic endometritis.

Fig. 4.—High-power view of cervical tissue (biopsy). Chronic cervicitis.

moved from the embedding substance and can be reblocked (for the purpose of securing permanent sections) by some other means, such as the slow paraffin method of impregnation.

Cutting.—The block can be sectioned easily by freehand cutting with an ordinary, sharp old-fashioned razor. With little experience satisfactory sections, measuring a fraction of a millimeter in thickness, can be obtained. Uniformly thinner and better sections can be obtained, however, by employing Terry's⁴ safety razor blade microtome. Wetting the block frequently facilitates cutting. Sections may be washed and stained immediately after cutting or they may be placed in water to prevent drying until convenient to stain.

Staining.—Terry's neutralized polychrome methylene blue is a most satisfactory preparation. Only one surface of a section is stained. Overstaining or staining more than one surface hinders proper transillumination and clear visualization of the tissue. To stain, place a section on a thin slab of wet sponge. If not previously washed, gently spurt a few drops of water on the exposed surface. Excessive water will be absorbed by the sponge. The stain may be painted on with a fine-pointed camel's-hair brush or sprayed on with an ordinary atomizer. Adequate staining is secured in from one to three seconds. The intensity and depth of staining are controlled by washing with water. As a rule, properly stained sections are secured by washing almost immediately after applying the stain. Washing is easily accomplished by spurling a medicine dropper or two full of water upon the stain-covered surface. The underlying sponge, if sufficiently wet, will absorb excessive stain and prevent staining of the undersurface of the section. After staining, the section must be mounted and examined immediately, since it fades fairly rapidly.

Mounting.—The section is placed on a cover slip with its stained surface next to the glass. The cover slip is then inverted and mounted on an ordinary microconcavity slide with the section in the cavity. It is now ready for transillumination and examination. If difficulty is experienced in transillumination, the section either is too thick or is overstained.

Examination.—While this method of preparing sections is most satisfactory for the examination of tissues under low-power magnification, excellent high-power views of most tissues can be obtained if the sections are thin enough and stained properly. Photomicrographs of sections prepared by this technique are generally unsatisfactory because of thickness of sections and the tendency of the stain to fade rapidly. Figs. 2, 3, and 4 are photomicrographs of sections photographed immediately after staining. Obviously, the interpretation of sections prepared by this method requires as much knowledge of histology and pathology as is needed for the correct interpretation of sections prepared by other methods.

SUMMARY

1. A technically simple, inexpensive method of preparing tissues for microscopic examination is presented.
2. The method is applicable in the office as well as in the laboratory.
3. Because of the time required for embedding, the method cannot be compared with frozen section technique for speed.

4. With little experience sections can be secured that are as good as, if not better than, the average frozen section.

5. Serial sections of biopsy specimens can be secured quickly and at less expense than by any other method I know.

6. This method should be particularly useful in the office practice of surgeons and gynecologists, who through adequate training, have acquired a good knowledge of micropathology. For instance, in my office it has been particularly useful for the examination of biopsy specimens of lesions of the vulva, vagina, and cervix, as well as for the examination of endometrium obtained by suction curettage.

A STUDY OF TYPE HEMOLYTIC REACTIONS OF HUMAN RED BLOOD CELLS IN DISEASE*

ELSIE WIECZOROWSKI, PH.D., AND H. R. FISHBACK, M.D., PH.D.
CHICAGO, ILL.

OF THE many methods and great variety of reagents that have been used to test the fragility of red blood cells only one has been found to have practical value as an aid in diagnosis. Hypotonic solutions of sodium chloride are used to test the fragility of erythrocytes in hemolytic jaundice and obstructive jaundice and have been reported as a prognostic guide in pneumonia.¹ This test has been applied to many diseases, but a review of literature does not reveal any systematic study in which several types of hemolytic agents were used to test the strength of red blood cells from a number of different diseases. This study is based upon the use of a comparatively short method which is adaptable for the use of several kinds of hemolytic agents. The method has been applied to red blood cells from normal individuals and patients with various diseases.

REAGENTS

As a neutral salt sodium chloride was used in hypotonic solutions. Its hemolytic property is believed to be due to osmosis, although various explana-

*From the Department of Pathology, Northwestern University Medical School, Chicago.
Received for publication, May 13, 1941.

tions are presented concerning its mode of action.^{2,3} Because it has been so widely used by other investigators, it is a good "yardstick" for comparison of results.

The hemolytic properties of acids and bases are believed to be due to a more complex action. It may be that they change the physical state of the cell proteins⁴ or that the action may be concerned with the respective H and OH ions of the acids and bases.⁵ Lactic acid and sodium carbonate were chosen to represent the acid and base hemolysins, respectively, because they are less toxic than the stronger agents of this group. A reaction which took place between lactic acid and the hemolysis products clouded the system and made accurate readings difficult. Because of this, it was excluded from this report.

Sodium oleate was used as a representative of the soaps whose lytic properties are now attributed to their action on proteins.⁴ This is contrary to the former interpretation, which considered the effects of those active hemolysins to be derived from their lipid solvent characteristics.

Saponin represented the glucoside lysins. Its hemolytic properties are probably due to its reaction with the cell proteins to a far greater extent than with the lipoids.

Alcohol was used as a lipid solvent hemolysin. It is a rather weak hemolysin, but gives a very definite end point. A protein precipitate forms in the system a short time after hemolysis is complete, but does not enter into consideration within the time limits of the method to be described.

METHOD

From 3 to 5 c.c. of blood were drawn from the antecubital vein into dry, sterile syringes and transferred immediately to sterile test tubes containing potassium oxalate. It was found that this anticoagulant does not alter the lytic properties of red blood cells. The cells of the fresh, oxalated blood were washed four times in 0.9 per cent sodium chloride solution and centrifuged ten minutes after each washing at a medium speed. At the rate used (1,400 to 1,500 r.p.m.) there is very little mechanical damage to the cells. An average of 2.4 c.c. of packed cells was recovered from 5 c.c. of normal blood. Suspensions of washed cells were prepared in the proportion of 2.4 c.c. of erythrocytes to 97.6 c.c. of 0.9 per cent sodium chloride solution.

TABLE I

AGENT	PER CENT CONCENTRATION									
	1	2	3	4	5	6	7	8	9	10
Test tube No.										
Sodium chloride	0.075	0.150	0.225	0.300	0.375	0.450	0.525	0.600	0.675	0.750
Saponin ($\times 10^{-2}$)	0.833	0.667	0.500	0.433	0.333	0.287	0.250	0.220	0.200	0.180
Sodium carbonate	0.225	0.180	0.135	0.090	0.067	0.037	0.030	0.022	0.015	0.007
Sodium oleate ($\times 10^{-2}$)	0.125	0.100	0.083	0.067	0.050	0.042	0.033	0.025	0.017	0.008
Ethyl alcohol	28.50	23.75	20.58	15.83	12.67	7.92	6.33	4.75	3.16	1.58

A series of ten hemolysis tubes was set up for each lysin, consecutively, using varied quantities of stock solutions with 0.9 per cent sodium chloride as diluent. These tubes, together with a tube of red blood cell suspension, were placed in a constant temperature bath set at $37^{\circ}\text{C.} \pm 0.2$ degree. When the contents of the tubes reached a temperature of 37°C. , an equal quantity of

the suspension was added to each tube of lysin and mixed by inverting once. All measurements were made with dry, chemically clean, burettes and pipettes. Care was used to keep all conditions as uniform as possible.

Table I shows the concentrations of each lysin.

The insulated water bath was arranged so that a strip of glass was left free across the front and back, with an equal distribution of light passing through the container. If hemolysis was completed in less than thirty minutes, the time necessary for completion was recorded. It is relatively simple to read complete hemolysis because the contents of the tube become clear. At the end of a half-hour period the degree of hemolysis in all tubes was estimated and recorded. The thirty-minute period proved optimum for securing hemolysis in a fairly wide dilution range of the lysins, and allowed less time for a new colloid-crystalloid adjustment in the cells, or for change of any hemolysis products set free in the tubes.

RESULTS

Average values for each lysin were first made by testing their effect on erythrocytes of normal individuals. Thirty-five persons were used, ranging in age from 5 to 84 years. The level of hemolysis of different individuals varied considerably, but variation in age had no significant effect on the reaction of the cells.

TABLE II
COMPLETE HEMOLYSIS

	NO.	SAPONIN	SODIUM CARBONATE	SODIUM OLEATE	ETHYL ALCOHOL	SODIUM CHLORIDE
Normal	35	0.342	0.066	0.055	15.24	0.219

± indicates statistical significance.

Tests were then made of the red blood cells of patients with various diseases. Table II gives a summary of the average values for beginning and completion of hemolysis.

DISCUSSION

In analyzing Table II two conditions are evident which lower the statistical significance of the results. One is the limited number of cases studied, only 35 for the normal figures, and still less for results in each of the diseases studied. It is realized that increasing the number of cases taken at random improves the statistical accuracy. Practically, however, one is limited as to the number of patients available. Furthermore, the objection as to numbers of cases is mitigated by the rather low swings from average in the individual case studies.

A further statistical objection relates to the lack of fineness of gradation in the hemolysis tests themselves when only ten tubes are used. However, the tests were formulated so that the hemolyzing zone would be found in the central tubes in normal cases. A swing to the right or left in abnormal cases would still be recorded within the given number of tubes. In a very large series of tests, adding still further to the number of tubes obviously would improve the statistical evidence of trends in the results within narrow limits, but would not improve the accuracy of the test.

It appears from the recorded results that the red blood cells are rather well adjusted to possible changes in the blood during disease. At least there is little evidence of variation from normal in the resistance of the cell when exposed to substances which affect either osmotic factors or protein or lipid constituents of the cells. Even when the averages were altered significantly, the range of concentration at which hemolysis occurred was, in most instances, within the range at which cells from normal persons were hemolyzed.

This seems to be the case in reports of other investigators also; that is, few have found any consistent reaction of the red blood cells that would be of diagnostic value. Trends are indicated but individual cases often vary from increased to decreased resistance when testing several cases with the same disease, as reported by Hill⁶ and Simmel⁷ on pernicious anemia. Randall⁸ found the red blood cell resistance in pernicious anemia to be decreased, while Giffin and Sanford,⁹ and Cassells¹⁰ report an increased resistance. On the other hand, Daland and Worthley¹¹ record normal maximum and decreased minimum resistance. All these investigators used hypotonic solutions of sodium chloride to test fragility. When saponin was the hemolysin, the reaction either was normal or showed a decrease in resistance.¹²⁻¹⁴

Needles¹ found a definite relationship in pneumonia between the resistance of red blood cells to hypotonic sodium chloride and the amount of lung tissue involved. Although there is a significant increase in mean resistance indicated in Table II, the data in these experiments show that many cases fall within normal range, and there is no such correlation of the resistance and extent of lung involvement.

Different results might have been obtained had the cells been unwashed, in which case possible changes in the serum would have played an important part. However, since this group of experiments was on the cells themselves, the serum had to be eliminated by washing in order to make the conditions of the experiment as uniform as possible.

SUMMARY

A method for testing fragility of red blood cells with a variety of type hemolytic agents is presented.

The hemolytic level of human red blood cells with various lysins is indifferent to the factor of age, from 5 to 84 years.

Results of applying this method to red blood cells from patients with pernicious anemia, secondary anemia, obstructive jaundice, pneumonia, scarlet fever, meningitis, sepsis, tuberculosis, carcinoma, sarcoma, and syphilis are recorded.

No significant changes of new diagnostic value were found in the erythrocytes with the method employed.

SIMPLIFIED METHOD FOR BIOLOGICAL DIAGNOSIS OF PREGNANCY*

S. ASCHHEIM, M.D., NEW YORK, N. Y.

THE biologic diagnosis of pregnancy, which I discovered in 1927, is based on the presence of gonadotropin in the urine and in the serum of pregnant women. My original method is as follows:

For the examination of every urine specimen, one needs five immature female mice, 3 to 4 weeks old and weighing 6 to 8 Gm. The total amounts injected subcutaneously into the five animals vary, but in every case six equal injections are made, distributed over forty-eight hours.

The first animal receives six times 0.2 c.c. (total 1.2 c.c.), the second animal six times 0.25 c.c. (total 1.5 c.c.), the third and fourth animals six times 0.3 c.c. (total 1.8 c.c.), and the fifth animal six times 0.4 c.c. (total 2.4 c.c.). Vaginal smears are made from the third day on. After ninety-six hours the animals are autopsied.

The ovaries are examined with the naked eye, or better, with a hand lens. The presence of hemorrhagic follicles and of corpora lutea is considered indicative of pregnancy. This method gives from 98 to 99 per cent correct results, and only from 1 to 2 per cent erroneous results.

Application of the same method to female immature rats does not give better results than with the mouse. All modifications of the method are based on the same principle, namely, looking for gonadotropin in the urine or the blood.

The modification of Friedman, which uses the adult female rabbit, can give a positive result twenty-four hours after intravenous injection of from 7 to 10 c.c. of urine. The modification of this Friedman method, as used by Brouha, gives the result in forty-eight hours. One injects 5 c.c. of urine on the first day, and 5 c.c. on the second day, into the ear vein of the female rabbit. Ovulation and the presence of hemorrhagic follicles are signs of the action of the gonadotropin.

Other modifications are the ones by Brouha-Simonnet^{1, 1a} and Kraus.² These authors use immature male mice or rats whose seminal vesicles increase in volume after daily injections of pregnancy urine during seven or eight days. This increase in the volume of the seminal vesicles is caused by the action of gonadotropin on the testicles, especially on the interstitial cells of Leydig, which manufacture the male hormone; this male hormone in turn produces an overgrowth of the seminal vesicles.

Bourg³ has employed a male rat and a female rat, both immature. He injects 1.1 c.c. of urine daily for five days and studies the seminal vesicles in the male and the ovaries in the female.

*Translated from the French by Alfred Plaut, Beth Israel Hospital, New York.
Received for publication, May 24, 1941.

Shapiro and Zwarenstein⁴ have employed the South African clawed toad, *Xenopus laevis*, as a test animal. After injection of pregnancy urine, the animal will lay eggs after ovulation has been stimulated. The result can be studied six to eight hours after the injection. Elkan⁵ has obtained satisfactory results with this method.

If I have tried to find a simplification of the method, my reason for this was not the hope of improving the results. External factors have induced me to look for a more economical method as far as material, working time, and expenses are concerned, in short, a method adapted to present conditions. The reasons are the following:

My original method with the five mice, and its modifications, require much work because injections have to be made frequently, and the same applies to the exploratory laparotomy in the female rabbit.

TABLE I

	NO. OF CASES	RAT TEST	RABBIT TEST	REMARKS
Normal pregnancy				
6-8 weeks	13	Of these 35 tests,	24 positive	Two false negatives with the rabbit test
9-12 weeks	11	33 were positive,	2 negative	
13-20 weeks	6	none negative.	2 rabbits died	
28-36 weeks	4	Two rats died	In 7 cases no rabbit test was made	
Unknown	1			
Abnormal pregnancy	1	Positive	Not made	
3 months tubal, one day after operation for rupture				
Two months tubal gestation	1	Positive	Positive	
Same case—5 weeks later	1	Negative	Negative	Operation revealed an old tubal abortion
Missed abortion (intrauterine)	1	Negative	Negative	
Nonpregnant women (amenorrhea, menorrhagia, menopause, castration, myomas)	30	Negative	10 not made 17 negative 3 positive	Three false negatives with the rabbit test In the menopause and after castration the rat test was negative even with 1 c.c. of urine
Teratoma of testicle	1	Negative	Negative	

NOTE: There were no false results with the new rat test (two rats died).

Buying the animals is expensive. That is why I have put to myself the question how it is possible to simplify the method by using immature female rats four to five weeks old.

Applying the original method to immature rats has never appeared advantageous to me. The hemorrhagic follicles are often absent, and sometimes the corpora lutea are difficult to distinguish from the interstitial tissue with the naked eye.

Why then did I choose the female rat as a test animal?

The Third International Conference on the Standardization of Hormones of the Health Organization of the League of Nations,⁶ at which I was present, recommended creating an international standard for the gonadotropic sub-

stance obtained from pregnancy urine. The Conference decided that the international unit would be defined as representing the specific gonadotropic activity of 0.1 mg. of a standard prepared by mixing numerous samples. This standard has been examined by numerous workers in order to determine its content of rat units.

It is agreed that a rat unit is the number of international units which produces in 50 per cent of the immature rats, injected subcutaneously during two or three days, vaginal keratinization. Formation of keratinized cells in vaginal smears is known as the Allen-Doisy test. It must be understood, however, that preparations of gonadotropin from pregnancy urine must not contain estrogen. The absence of estrogen can be proved by injecting the gonadotropin into castrated animals. Under these conditions the method for determination of gonadotropin in pregnancy urine can be used for commercial preparations in spite of the fact that the method is based on an indirect effect and not on an ovarian change. In the method I have called the simplified method of the pregnancy reaction, I rely entirely upon vaginal smears (the Allen-Doisy test) without entering into the question whether the reaction is caused by gonadotropin in the urine or by estrogen. As I have shown, the estrogen also is present in considerable quantity in the pregnancy urine. It also is possible that both hormones act simultaneously.

The method is the following: To two female immature rats, 4 to 5 weeks old, weighing 22 to 35 Gm. (the weight figures apply only to our strain), one subcutaneous injection of 0.5 c.c. of the urine to be examined is given. Vaginal smears of both rats are made seventy-two, eighty-four, and ninety-six hours after this single injection.

If the urine comes from a pregnant woman, only epithelial cells without free mucus and without leucocytes in the vaginal smear are found after seventy-two hours (often already after sixty-six hours). After eighty-four to ninety-six hours keratinized cells (seldom mixed with a few epithelial cells) are found. The keratinized cells constitute the criterion of the positive reaction.

The animals need not be killed. They may be used for other experiments, for instance castration.

If an autopsy is performed, easily visible follicles in the ovaries are found. Corpora lutea are seldom seen, and the uterus is found enlarged. Since animals of the same age and weight, which have not been injected, may also show visible follicles, this fact is not of diagnostic value. Only the fact that the vaginal smears contain the keratinized cells after a single injection of 0.5 c.c. of urine is important and can be used for the diagnosis of pregnancy.

The following objections may be raised against this method:

1. The Allen-Doisy test proves only an estrogenic effect. In the castrated animal (rat, mouse) it proves that the fluid injected contains an estrogenic substance.

In the noncastrated immature animal the Allen test indicates that in the injected fluid there is either an estrogenic substance acting directly on the vagina or a gonadotropic follicle-stimulating substance which acts by the intermediation of the ovary on the vagina. Or, finally, a hypophyseotropic substance which

stimulates the anterior lobe of the pituitary and makes it produce and secrete follicle-stimulating hormone. This substance thus would act upon the vagina by way of two intermediary organs, namely, the pituitary and the ovary.

Estrogenic substance is not eliminated in the urine in sufficient quantity, so that 0.5 c.c. in a single subcutaneous injection could lead to a positive Allen-Doisy test except in pregnancy. Normal women excrete less than 1,000 units. The presence of from 300 to 500 mouse units per liter indicates abnormally increased secretion of estrogen.

The amount of estrogen also is increased in women who bear granulosa cell tumors of the ovary. Several hundred mouse units have been found per liter of urine, but so far one has not observed an excretion of 6,000 units per liter, and this is the minimum necessary for giving a positive reaction in the immature rat after a single injection of 0.5 c.c. The abnormal estrogen secretion which sometimes is found in women who have follicular cysts, or fibrocystic ovaries, remains below 6,000 mouse units per liter.

Only in the second half of pregnancy does the elimination of estrogenic substance rise to several thousand mouse units (6,000 to 40,000, and higher) per liter of urine.

Thus, if an immature rat, after receiving an injection of 0.5 c.c. of urine of a woman, gives a positive Allen-Doisy test, one can conclude that it was the urine of a pregnant woman that has produced this reaction.

2. One can object that the follicle-stimulating gonadotropic substance of hypophyseal origin, which also is eliminated with the urine, might falsify results. But this elimination usually does not exceed 30 rat units per liter; it seldom reaches 75 rat units in the normal woman. In women with physiologic or artificial menopause (operation or x-ray) the amount of follicle-stimulating hormone is elevated in the urine. But so far no elevation to 2,000 rat units, which would correspond to 4,000 mouse units, has been found. The highest known figures are 1,000 mouse units. One rat unit of the follicle-stimulating hormone corresponds to two or three mouse units; conversely, in the case of gonadotropin obtained from pregnancy urine (placental origin), one mouse unit corresponds to five rat units.

Occasionally women with primary amenorrhea eliminate gonadotropic follicle-stimulating substance in a large amount, but in my experience not more than 1,000 mouse units. Furthermore, clinically in these women who always have an atrophic uterus, the question of pregnancy does not present itself.

3. Increased elimination of follicle-stimulating hormone (and seldom also of luteinizing hormone) in women with cancer of the cervix or cancer of the vulva has been observed. I have examined about 100 such women, most of whom were in menopause. I have seldom found increased elimination in cancer patients who still menstruated. The figures in these cases did not exceed 1,000 mouse units. I have not yet done quantitative studies of these cases with immature rats, but I do not believe that we could obtain a wrong result with this simplified method by injecting only 0.5 c.c. of urine.

4. The cases of persisting corpus luteum sometimes have given a positive reaction with mice or rabbits. These cases are very rare and one has to wait

a long time before one encounters a case in which the differential diagnosis between extrauterine pregnancy and persistent corpus luteum is of importance. In such cases the simplified method perhaps will be better than the other methods.

5. Cases of chorio-epithelioma and of teratomas of ovaries, and of other organs which give a positive reaction in the mouse and the rabbit, have not yet been examined with the rat method. In tumors which contain chorionic cells no biologic method can give a differential diagnosis between pregnancy and tumor.

6. The combined excretion of estrogen and gonadotropin in quantities, which would give a positive reaction, in our present stage of knowledge cannot be expected, except for chorio-epithelioma or teratoma.

The physician must know that such rare cases exist and must consider them during his clinical examination.

The biologic pregnancy test must not replace exact clinical examination. Close collaboration between the physician and the laboratory man is always necessary.

Thus, we have seen that all the objections against the simplified method can be refuted.

I have chosen 0.5 c.c. for injection. In some cases I have injected only 0.2 c.c., and I have obtained positive results, except in one case in which 0.5 c.c. gave a positive result while with 0.2 c.c. the result was negative. I must continue these tests for if a lower dose than 0.5 c.c. should give the same results, all objections against the method would become even weaker. Meanwhile, I propose the dosage of 0.5 c.c.

In five cases of pregnancy I have given a single injection of 1 or 2 c.c. of urine to male immature rats in order to see whether or not the simplified method is also applicable to the male. This method would have to be based on the increase in size of the seminal vesicles (Brouha-Simonnet, Kraus). Since I could not see such an increase ninety-six hours after the injection, I believe that the simplified method cannot be applied to the male immature rat.

AN IMPROVED POLYCHROME METHYLENE BLUE EOSINATE*

LOUIS MICHELSON, BETHESDA, MD.

CONSIDERABLE variation in the effectiveness of staining malaria parasites is found in using different lots of Wright's stain purchased on the open market. Frequently malaria parasites stained by Wright's technique are either understained or are otherwise poorly differentiated. Experiments reported here were undertaken in an attempt to produce a stain with a strong affinity for blood parasites. Several eosinates of methylene blue polychromed with various agents were made and tested. The eosinate of methylene blue polychromed with sodium hydroxide was found to be unstable and of inferior staining quality. However, methylene blue polychromed with sodium hydroxide and then treated with sodium bromide, prior to the addition of the eosin solution, proved effective. Six lots prepared by this procedure have given the desired staining effect, and after more than six months each lot is still stable both in powder and in solution. It is believed, therefore, that this technique provides a reliable method for uniform staining of blood parasites.

The stain is prepared as follows: One gram of methylene blue chloride (certified) is dissolved in 100 c.c. of N/100 sodium hydroxide (carbonate free) in a ground glass-stoppered bottle of about 500 c.c. capacity. Best results are obtained when not more than one-quarter of the bottle is filled by the solution during the polychroming process. The solution is heated in a water bath at 55° C. for two and one-half hours. The bottle stopper is loosened slightly before heating and at half-hour intervals the solution is shaken vigorously for about a minute. At the end of two and one-half hours, 1 Gm. of sodium bromide is added and dissolved in the polychromed methylene blue, and the solution is again heated in the water bath for another two and one-half hours, allowed to cool, and filtered.

To the polychromed methylene blue filtrate is added 60 c.c. of a 1 per cent aqueous solution of eosin "Y" (certified water and alcohol soluble), and mixed well with a glass stirring rod. More eosin is added in 5 c.c. amounts until the solution between the precipitated particles has a reddish tinge. This is best observed by letting a little of the precipitate from the solution run down the inside of the upper portion of the beaker. Generally, about 80 c.c. of the eosin solution give the desired maximum precipitation of the eosinate. The precipitate is allowed to stand for from eighteen to twenty-four hours. The precipitate is then collected on hard filter paper in a Buchner funnel with vacuum until the precipitate is sufficiently dry to crack. The precipitate is allowed to dry completely in the incubator at 37° C., and then ground to a fine powder in a mortar. The powder is stored in a small tightly stoppered glass bottle.

*From the Division of Infectious Diseases, National Institute of Health, Bethesda.
Received for publication, May 24, 1941.

In making the stain 0.1 Gm. of the powder is dissolved in 60 c.c. of absolute methyl alcohol, acetone free. The stain is allowed to stand two to three days, occasionally shaken, until the dye appears to be completely dissolved. The stain solution is filtered and stored in a small tightly stoppered bottle.

STAINING TECHNIQUE

1. Cover a thin blood film with 0.5 c.c. of stain and allow to fix for one minute.

2. Dilute the stain with 2 c.c. of phosphate buffer solution, mix thoroughly, and allow to stain for three minutes. A pH range of 6.4 to 7.0 for the phosphate buffer diluent is satisfactory. When suitable diluent is added, an iridescent scum is formed over the stain. Best staining results are obtained with freshly made diluents, not more than one week old.

3. Wash by flooding with distilled water. Air dry and examine.

This technique is simple and rapid, and has yielded uniform and superior results. It is easy to obtain stained preparations free from precipitated stain.

CHEMICAL

A COMPARISON OF THE BODANSKY AND FISKE-SUBBAROW METHODS FOR THE DETERMINATION OF INORGANIC PHOSPHORUS*

JOSEPH M. LOONEY, M.D., AND CORA G. DYER, M.S., M.T.
WORCESTER, MASS.

DURING the course of our investigations of the physiologic functions in schizophrenic patients, a study was made of the serum phosphatase levels. This necessitated a change in the technique of phosphorus determinations from the Fiske-Subbarow¹ method previously used to that of Bodansky.^{2, 3} As the phosphorus values seemed to run lower by the new method, duplicate analyses of 19 sera were made by the two methods. The results of these analyses are given in Table I. The values given under the stannous chloride method have been corrected in accordance with the instructions of Bodansky. Because two cases did not have duplicates by both methods, the statistical analysis was carried out for only 17 samples.

It will be noted that despite these corrections the use of the Bodansky technique gives lower values than that of Fiske and Subbarow. The correlation between the two methods is 0.87, and the values of the Fiske method can be calculated from those obtained by the Bodansky technique after applying his corrections by applying the following regression equation:

$$Y = 0.7784 X + 0.9511$$

where Y = inorganic phosphorus Fiske, and

X = inorganic phosphorus Bodansky corrected.

The equation for the uncorrected Bodansky value is

$$Y = 0.973 X' + 0.327,$$

where X' is the uncorrected Bodansky value. The error of estimation by these equations is ± 0.18 mg.

The mean value obtained by the Bodansky method was 3.12 ± 0.1 mg. per cent, while that by the Fiske method was 3.31 ± 0.1 . These values were from a group of chronic schizophrenic patients and are lower than those found in the acute stage of the disease.⁴

Since the two series show a high correlation, in order to test for significance of the difference between the means, it is necessary to use the expanded formula for the standard error of the difference:

$$\sqrt{E_1^2 + E_2^2 - 2r(E_1E_2)}$$

where E_1 and E_2 are the standard errors of the means, and r is the correlation coefficient between the two sets of observations. In this case the standard error

*From the Memorial Foundation for Neuro-Endocrine Research and the Research Service of the Worcester State Hospital, Worcester.
Received for publication, November 3, 1941.

of the difference is 0.051, and since the difference between the means is 0.19, the ratio between these is 3.73, which is highly significant. The probability that this difference could occur by chance is less than 0.0003.

The duplicate determinations by the Fiske method using 1, 2, 4 aminonaphthosulfonic acid as the reducing agent show much closer agreement than do those using stannous chloride. The variance within samples for the first method was 0.0045, while that for the second method was 0.0138. This difference in variance of three times is highly significant in a sample of 17 duplicates, and indicates that the precision of the Fiske method is much higher than that of the Bodansky method.

The reduction by stannous chloride was followed in the photoelectric colorimeter. The maximum reduction occurred almost instantaneously and remained constant for approximately ten minutes. Slight variations in the strength of acid or molybdate produce marked changes in the depth of color. These changes are not so important when the unknown is read against a standard solution but can lead to considerable errors when read in a photoelectric colorimeter and

compared to a standard curve. The method, however, is about six times more sensitive than the Fiske method, so that determinations can be made on smaller amounts of material.

The deviation from Beer's law is due to the reduction of the uncombined molybdic acid, and the precautions outlined by Bodansky must be followed in order to minimize this reduction, as shown in the blank. All alkaline solutions must be stored in paraffined bottles and the N 10 sulfuric acid should be kept in a pyrex glass container to prevent the contamination of the solutions by silicates. This effect of silicates has been noted by Roe and Whitmore.⁵

Berenblum and Chain^{6, 7} have noted similar difficulties in the use of stannous chloride as a reducer and have devised a method for overcoming this by extracting the combined phosphomolybdic acid with isobutyl alcohol to remove the excess of molybdic acid. This method, though capable of giving accurate results on dilute solutions, requires several extractions and washings, which are somewhat of a nuisance when many determinations must be carried out.

SUMMARY

Duplicate analyses for inorganic phosphorus were made on sera from 17 schizophrenic patients by both the Fiske-Subbarow and the Bodansky methods. Readings were made on a Lange photoelectric colorimeter. The deviation from Beer's law produced in the Bodansky method, using stannous chloride as the reducing agent, is not completely compensated for by the corrections applied by Bodansky. The variance of the Bodansky method is 0.0138 as compared with 0.0045 for the Fiske-Subbarow method.

By the use of a photoelectric colorimeter and comparison with a standard curve, the error of the Bodansky method due to deviations from Beer's law may be kept at a minimum provided that extreme care is taken in duplicating the reagents used. A known phosphorus standard should be included in each series of unknowns as a check on the reagents. If a photoelectric colorimeter is not available, reasonably accurate estimations can be made by application of one of the formulas given to the values obtained with a Duboseq type colorimeter.

ESTIMATION OF VITAMIN D IN BLOOD SERUM*

VITAMIN D IN HUMAN SERUM DURING AND AFTER PERIODS OF INGESTION OF LARGE DOSES OF VITAMIN D

JOSEF WARKANY, M.D., GEORGE M. GUEST, M.D., AND
FRANK J. GRABILL, M.S., CINCINNATI, OHIO

IN THE two preceding papers of this series^{1, 2} a method for the estimation of the vitamin D content of blood serum was described, and data were presented on the vitamin D content of blood sera from persons taking a normal diet without added vitamin D. In 155 samples of such human blood serum the average concentration of vitamin D was found to be 110 U.S.P. units per 100 c.c.; but values between 66 and 165 units per 100 c.c. were regarded as within normal limits, especially when assays of individual samples of serum were based on a small number of line tests. No significant difference was found between the vitamin D content of sera of normal children at ages beyond infancy and the sera of adults.

The present report deals with similar assays of the concentration of vitamin D in the blood serum of adult patients examined at varying intervals during and after periods in which large daily doses of vitamin D were prescribed. These persons were suffering with mild or moderately severe chronic proliferative arthritis of several years' duration. For the opportunity to study them we are indebted to Dr. Stanley E. Dorst, of the Department of Medicine of the University of Cincinnati. While these patients were treated with vitamin D, it was thought that the assay of the vitamin D content of their blood sera at different times might add information concerning the metabolism of vitamin D in the body. The use of large doses of vitamin D in the treatment of chronic arthritis has been described by numerous authors (see review of this subject by Abrams and Bauer³). It is not our purpose to discuss here the merits or demerits of this form of therapy, but merely to describe the changes in concentration of vitamin D which were found in the blood serum of these patients following the ingestion of large doses of vitamin D. Assays of vitamin D in single samples of blood serum from children receiving equally large daily doses of vitamin D for various therapeutic reasons have yielded data essentially similar to those reported here.

For use in these investigations two preparations were supplied by the manufacturers. The Winthrop Chemical Company, New York, furnished a solution

*From the Children's Hospital Research Foundation and the Department of Pediatrics, University of Cincinnati College of Medicine, Cincinnati.
Received for publication, December 14, 1940.

of crystalline vitamin D₂ in oil, 1,000,000 units per gram, and the W. S. Merrell Company, Cincinnati, furnished capsules each containing 50,000 units of vitamin in oil.

METHODS

In biological assays of blood sera, which may vary considerably in vitamin D content, it is useful to perform preliminary tests to ascertain the range in which the vitamin D concentration falls. Another assay is then performed by administering to a series of rats different amounts of serum, varying by smaller increments within the range of dosage established by the preliminary test. If the results of duplicate line tests in this series do not prove uniform, a third assay may be necessary. Since several weeks may elapse sometimes before the final results are obtained, it is important to prevent bacterial contamination of the serum and also to prevent deterioration of its vitamin D content. Both objectives have been achieved by freezing and drying the serum, either the whole sample or the portion not used in the preliminary assay. Such dried serum samples can be stored and then dissolved at any convenient time when needed for further assays. The drying of the serum offers another advantage if the vitamin D content of the serum is low. In such cases the amounts of serum required to initiate healing in rachitic rats may be so large that its administration to the rats may be difficult. Since the dried material can be redissolved easily in one-fifth its original volume of water, the volume of the serum to be administered can be greatly reduced. This smaller volume also makes possible the administration of the serum directly to the rats in doses accurately measured by pipette, a method of administration preferable to mixing a test material with the rachitogenic diet.

METHOD AND PROCEDURE FOR DRYING SERUM

A method of drying of biological materials in the frozen state has been described by Shackell⁴ as early as 1909. The desiccation of sera and other biological products, including microorganisms, in the frozen state was accomplished by Elser, Thomas, and Steffen.⁵ The method was further developed by Flosdorf and Mudd.⁶ For our purpose a simple and inexpensive method was desirable, and we used an apparatus and a procedure which are essentially identical with that described by Cooper and Grabill,⁷ the only difference being that vials of serum are substituted for the bacterial cultures. In this method the serum is first frozen in a dry ice bath and then dried in vacuo, the water being absorbed by a suitable chemical desiccant. The availability of the apparatus, its simplicity of construction and operation, and the economy in time, together with the satisfactory results obtained, prompted us to employ it.

The equipment for the drying of the serum consists of a vacuum pump, a Wouff Bottle of 2 liter capacity, serum vials with stoppers* (Fig. 1), a desiccant such as "Drierite," glass connections, and other accessories, such as rubber stoppers and pressure tubing. Our routine procedure is as follows:

Five cubic centimeters of human serum are frozen in 10 c.c. vials in a position illustrated in Fig. 1A. In order to insure the proper drying conditions,

*The serum vial stoppers were purchased from the F. J. Stokes Machine Co., Philadelphia, Pa.

the liquid serum should never occupy more than one-half the volume of the container. It is essential to establish a relationship between the volume of serum and the evaporating surface; the depth of the serum at the time of freezing should not exceed 15 mm. By rotation the serum may be shelled in the container while freezing in order to increase the evaporating surface during the desiccation process. The dry ice bath is prepared by adding crushed dry ice to a liquid which does not freeze above $-72^{\circ}\text{C}.$; alcohol or acetone is suitable. When the bath has become completely cooled, which is indicated by the absence of carbon dioxide bubbles, the vials containing the serum are submerged (Fig. 1A) and allowed to remain in the bath for approximately thirty minutes. After freezing,

Fig. 1.—Schematic representation of the manner in which blood serum is (A) frozen and (B) dried.

the serum is quickly connected by means of the rubber stopper to the Wouff Bottle, which has been equipped with tight rubber stoppers and T-tube connections (glass) for the serum vials (Fig. 1B). The Wouff Bottle contains approximately 4 pounds of regenerated "Drierite." Simultaneously with the attachment or before, the vacuum pump is started. If the system is free from leaks, the moisture in the frozen serum will sublime to the chemical desiccant. As the moisture evaporates from the surface of the frozen serum, the removal of heat by vaporization is sufficient to retain the serum in the frozen state throughout the period of desiccation. Frost collects on the outside of the containers within seven minutes. The use of the stopcock grease on all connections was found desirable; first, to secure high vacuum throughout the system, and second, to facilitate the rapid attachment of the vials to the Wouff Bottle. The vacuum pump is allowed to maintain the vacuum of the system for a total of eighteen to twenty hours to insure complete drying. At the end of this period the metal sealing bands surrounding the necks of the rubber bottle are then severed from the and sealed in a vacuum is stored in a cold room until the time of feeding.

Before making use of the process of freezing and drying of blood sera for the purpose of preservation, it was first necessary to determine whether the anti-

rachitic potency of serum was altered by this procedure. A number of sera were assayed immediately after the sample was taken and tested again after various periods of storage in the dried stage. No significant change of the vitamin D content was noticed even after one year of storage.

OBSERVATIONS

Charts 1 to 6 indicate the daily doses of vitamin D administered and the concentration of vitamin D found in the blood serums at different times during and after treatment of each of six patients.

Chart 1.—Vitamin D level in blood serum of W. K. during oral administration of 50,000 units of vitamin D daily. N indicates the average vitamin D level in normal human blood serum (110 units per 100 c.c.)

In all charts the line indicates the vitamin D level in blood serum and the solid black portion indicates dosage.

CASE 1, Chart 1. W. K., white female, 45 years of age, was given 50,000 units of viosterol daily for six months. Due to an insufficient amount of sample, an incomplete assay was made of the blood serum obtained before the treatment was started. It was assumed, however, for making the chart, that the initial concentration of vitamin D in the blood serum was around 110 U.S.P. units per 100 c.c., corresponding to that found in other untreated persons previously reported. In the sample of serum obtained thirty-five days after the start of treatment, the concentration of vitamin D was 1,650 units per 100 c.c. With the same dosage continued, the concentration of vitamin D in the serum progressively decreased to 830, 660, and 330 units per 100 c.c., at two and one-half months, four months, and six months, respectively, after the start of treatment.

CASE 2, Chart 2. A. H. S., white male, 76 years of age, was given 150,000 units of crystalline vitamin D₂ daily during two and one-half months. In one month the concentration of vitamin D in his blood serum rose to 6,600 U.S.P. units per 100 c.c., remained constant eighteen days, and then decreased to 4,400 units per 100 c.c. before the treatment was discontinued. Two and a half months later the concentration of vitamin D in the blood serum had decreased to 1,700 units per 100 c.c. No further blood samples were taken thereafter for assay.

CASE 3, Chart 3. A. M., colored female, 43 years of age, took 180,000 units of vitamin D₂ daily for thirty-one days, and then discontinued treatment for eleven days. She then took 240,000 units of the same preparation daily for twenty-nine days. During the first period of medication the concentration of vitamin D in her blood serum rose to 3,300 units per 100 c.c., but fell to 1,600 units per 100 c.c. at the end of the eleven-day period without medication. At the end of the second period of medication the concentration again was 3,300 units per 100 c.c. Subsequently, the concentration of vitamin D in the blood serum fell to 1,600 units per 100 c.c. at the end of one month, to 800 at the end of two months, and to 330 at three and one-half months after the treatment was stopped.

CASE 4, Chart 4. H. R., colored female, 30 years of age, was given 200,000 units of viosterol daily for five days, then 300,000 units for twelve days, and 400,000 units daily thereafter for four months. The vitamin D in her blood serum increased rapidly to a concentration of 13,000 units per 100 c.c., two and one-half months after the treatment was started. Thereafter the concentration decreased, falling to around 8,000 units per 100 c.c.

Chart 2.—Vitamin D level in blood serum of A. H. S. after oral administration of 150,000 units of vitamin D daily.

Chart 3.—Vitamin D level in blood serum of A. M. after oral administration of 180,000 to 240,000 units of vitamin D daily.

Chart 4.—Vitamin D level in blood serum of H. R. after oral administration of 400,000 units of vitamin D daily.

at the time the treatment was discontinued. After this date the concentration decreased to 5,500 units per 100 c.c. in one month, and to 330 units per 100 c.c. in four months.

CASE 5, Chart 5. E. B., white female, 36 years of age, was given viosterol in doses as follows: 150,000 units daily for three days, 300,000 units daily for seven days, 400,000 units daily for fourteen days, and 500,000 units daily for eighteen days. Thirst and polyuria developed, and the daily dose was decreased to 400,000 units, which she took during the following ten days. She then developed an infection of the respiratory tract and medication was stopped for five weeks. After this interval she again was given 400,000 units of the same preparation daily for forty days; no unfavorable symptoms developed. During the first period of medication the concentration of vitamin D in the blood serum increased to over 9,000 units

Chart 5.—Vitamin D level in blood serum of E. B. after oral administration of 150,000 to 500,000 units of vitamin D daily.

per 100 c.c., but decreased to 6,600 units per 100 c.c. in the sample taken at the end of the first period when 400,000 units were taken daily. During the period when 500,000 units were taken daily, the concentration again rose to above 9,000 units per 100 c.c. In the sample obtained after thirty days without medication, the concentration of vitamin D in the serum had fallen to 3,300 units per 100 c.c., and this concentration continued to decrease in spite of the resumption of daily doses of 400,000 units. Since this patient lived at home, it is, of course, possible that she did not take the medicine as prescribed, although she claimed that she had taken it faithfully.

CASE 6, Chart 6. G. B., white male, 54 years of age, was given two preparations of vitamin D in three different periods. In the first period viosterol was given daily as follows: 200,000 units for four days; 300,000 units for ten days; 400,000 units for seven days; 500,000 units for fourteen days; and 450,000 units for five days. Because of the development of thirst, polyuria, and slight nausea, medication was stopped. Seventeen days later he was given crystalline vitamin D₂, 450,000 units daily for ten days. Nausea returned and medication was stopped for six months. In a third period viosterol was given in smaller doses: 50,000 units daily for eighteen days; 150,000 units for twenty-five days; and 200,000 units daily for five months. In Chart 6 are represented the changes in concentration of vitamin D in the blood serum during these successive periods with and without medication. In the first period the concentration rose to 13,200 units per 100 c.c., and then fell to 6,600 units per 100 c.c. at the end of the first rest period of seventeen days. During the second period, ten days, the concentration of vitamin D in the serum fell to 4,400 units per 100 c.c., although the patient again developed symptoms of intoxication. During the long rest period the con-

centration of vitamin D in the serum gradually fell to 330 units per 100 c.c. During the third period of medication the concentration of vitamin D in the blood serum rose to 4,400 units per 100 c.c., and then gradually decreased again in spite of the continued constant daily dose of viosterol.

Chart 6.—Vitamin D level in blood serum of G. B. after oral administration of 200,000 to 500,000 units of vitamin D daily.

DISCUSSION

Prolonged oral administration of large doses of vitamin D (50,000 to 500,000 International units daily) to adult patients led to an increase in the antirachitic potency of their blood serum. The highest potency observed was more than one hundred times that of normal human blood serum. Such a concentration of vitamin D in the serum, equal to that of cod-liver oil, was tolerated by patient H. R. for more than two and a half months without any symptoms of intoxication, but another patient (G. B.) complained of thirst, polyuria, and nausea when a similar level of vitamin D in his serum was reached. The concentration of vitamin D in the serum was roughly proportional to the daily dose of vitamin D administered. This fact is demonstrated by Charts 1 to 6, previously discussed, and by data in Table I. Calculations of the vitamin D content of the entire volume of blood serum at the time when the concentration was at its maximum were based on the concentration of vitamin D per 100 c.c. of serum, the body weight, the blood volume (assumed to be $\frac{1}{12}$ the body weight), and the per cent volume of cells in the blood (determined by centrifugation of a sample of heparinized blood, obtained at the same time as the sample used for serum vitamin D determination). In Table I are listed the amounts of vitamin D thus calculated to be present in the entire blood serum of each of six patients, and the daily dose of vitamin D each was taking when the concentration of vitamin D reached the highest level in the serum. In three patients (W. K., H. R., and G. B.) the maximal accumulation of vitamin D determined in the entire blood

serum corresponded closely to the amount that was being ingested daily. Four charts (1, 2, 4, and 6) suggest, however, that the maximal concentration of vitamin D in the serum was not maintained throughout the period during which the administration of large daily doses was continued. In Case 5, when the daily dose of 400,000 I. U. was discontinued, the concentration of vitamin D in the serum promptly decreased, as was to be expected. When the same dose was resumed, the concentration of vitamin D in the serum did not return to its previous level. Such findings might be interpreted to mean a diminishing absorption of the drug, increased excretion, or a more rapid rate of destruction of vitamin D in the body. Further studies would be required to determine which of these explanations is the most probable.

TABLE I

PATIENT	DAILY DOSES (I.U.)	CALCULATED AMOUNT OF VITAMIN D IN ENTIRE BLOOD SERUM OF PATIENT (I.U.)
W. K.	50,000	54,000
A. H. S.	150,000	220,000
A. M.	180,000	110,000
H. R.	400,000	350,000
E. B.	400,000	186,000
G. B.	450,000	460,000

In most of the blood samples drawn from these patients for assay of the vitamin D in the serum, the distribution of inorganic and organic acid-soluble phosphorus in the serum and cells also was determined.* Although these data are not reported, it is germane to note here that the changes in distribution of phosphorus, such as were found in the bloods of these patients during their courses of treatment, were only slight and of doubtful significance. These investigations were made because of earlier findings that in some conditions vitamin D therapy brought about large changes in the concentration of both inorganic and organic phosphates in the blood. In rachitic animals with low concentrations of inorganic phosphorus in the blood serum and of phosphoric esters in the blood cells, the distribution of phosphorus in the blood became normal following the administration of small curative doses of vitamin D⁸⁻¹⁰. In normal rabbits the administration of large doses of irradiated ergosterol led to great increases of inorganic phosphorus in the whole blood and of organic acid-soluble phosphorus in the blood cells,¹¹ mainly accounted for in the diphosphoglycerate fraction.¹² The doses of irradiated ergosterol, which provoked such changes in the distribution of phosphorus in the blood of rabbits, were, however, much larger in proportion to body weight than the doses administered to the patients here reported. Moreover, the marked chemical changes of the bloods of rabbits were accompanied by definite signs of intoxication, such as loss of weight and hyperazotemia. No attempt was made to increase the doses of vitamin D given the patients to amounts causing more than very mild symptoms of intoxication. It is noteworthy that the concentration of vitamin D in the blood may be increased to many times the normal level without much, if any, change in the distribution of phosphorus in the blood.

*With the cooperation of Dr. S. Rapoport.

SUMMARY

A method of freezing and drying blood serum, which permits preservation and concentration of the serum without alteration of its vitamin D content, is described.

Data are reported on the vitamin D content of the blood serum of six adult patients during and after periods of taking large doses of vitamin D (50,000 to 500,000 International units daily).

During periods in which the daily high dose of vitamin D was constant, the concentration of vitamin D in the blood serum increased rapidly to a maximal level, which was roughly proportional to the daily dose. After doses of 400,000 to 500,000 units daily the concentration of vitamin D in the serum rose to between 9,000 and 13,000 I. U. per 100 c.c.; in other words, to an antirachitic potency equal to that of cod-liver oil. Few toxic symptoms were observed in the patients who took such doses of vitamin D.

During periods in which the daily high dose of vitamin D was constant there appeared to be a tendency for the concentration of vitamin D in the serum to decrease somewhat after attaining a maximal concentration.

After abrupt withdrawal of the high daily doses of vitamin D from three to six months elapsed before the concentration of vitamin D in the blood serum fell to a normal level.

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

BLOOD: Blood Cells in Healthy Young Infants, Washburn, A. H. *Am. J. Dis. Child.* 62: 530, 1941.

A description is given of the postnatal readjustments in the red blood cell values of 15 healthy infants during the first ten to eighteen weeks of life.

The simple explanation advanced for the observed changes is based on the comparison of the weekly values for the red blood cell count, the reticulocyte count, and the body weight for each individual baby. The comparison led to the conclusion that the decrease in the red blood cell count, the hemoglobin content, and the volume of packed cells in the first six to nine weeks of life is dependent largely on two factors.

The first factor is the rapid increase in total body mass. This appears to involve a similar rate of increase in total blood volume, so that the ensuing dilution results in fewer red blood cells per cubic millimeter of blood.

The second factor is the abrupt decrease in reticulocytes, indicating a sudden decrease in the rate of production of red blood cells. In most babies the rate of production between the ages of 1 week and 5 or 6 weeks appears to be too low for maintenance of the red blood cell level in the blood, especially in the presence of an increasing plasma volume.

The decrease in the number of red blood cells and in the amount of hemoglobin per cubic millimeter of blood results in a rise in the reticulocyte percentage at about the fifth to eighth week. The sharpness and the persistence of the rise in different babies vary, roughly, with the rapidity of weight gain and the speed of decrease in the red blood cell count.

In most babies the red blood cell count starts to increase between the sixth and the tenth week of life and continues to rise until it reaches a level of between 4,500,000 and 5,500,000 at about 16 weeks of age. Meanwhile, the number of reticulocytes decreases to approximately 1.0 per cent.

It seems probable that the period of postnatal adjustment of the red blood cells for most healthy babies extends over the first fifteen to twenty weeks of life.

LEUKEMIA, Erythroblastic, Stransky, E., and Quintos, F. N. *Am. J. Dis. Child.* 62: 577, 1941.

The case of a girl, aged 2 years 3 months with chronic myelogenous leucemia is presented. The patient died thirty-one hours after admission to the hospital. The observations on the blood and the bone marrow, as well as the histologic sections, were characteristic of chronic myelogenous leucemia. The most striking feature in the case was the marked erythroblastosis. There were 61,000 nucleated red blood cells per cubic millimeter in the peripheral blood and more than 280,000 in the bone marrow. The majority of the nucleated red blood cells were normoblasts. The clinical diagnosis was chronic myelogenous leucemia, and the hematologic diagnosis was severe erythroblastic anemia with chronic myelogenous leucemia; the final diagnosis in the case was erythroblastic leucemia. The similarity between the data in this case and those in cases of the so-called erythroleucoblastic type of hydrops foetalis congenitus is discussed. The unknown cause of chronic myelogenous leucemia may stimulate not only the granulocytopoietic tissue but, exceptionally, the erythropoietic tissue of the bone marrow.

BLOOD LOSS, Response of Normal Subjects to, Ebert, R. V., Stead, E. A., and Gibson, J. G. II. Arch. Int. Med. 68: 578, 1941.

Seven hundred and sixty to 1,220 c.c. of blood (15.5 to 19.7 per cent of the total blood volume as determined by the plasma volume and the hematocrit reading) were removed from 6 normal persons in six to thirteen minutes. In 5 of the 6 there developed collapse, characterized by weakness, nausea, blurred vision, pallor, sweating, and fall in arterial pressure. Before the onset of collapse the heart rate increased from 14 to 30 beats per minute. At the height of collapse the heart rate became slow, ranging between 36 and 40 beats per minute.

The plasma volume began to increase immediately after hemorrhage and continued to increase for the next forty-eight to seventy-two hours. At the end of seventy-two hours it was approximately equal to the plasma volume before hemorrhage plus the volume of red blood cells removed.

During the first two hours after venesection the plasma volume was increased by protein-poor fluid, so that the serum protein concentration decreased. Thereafter, fluid and protein were added to the plasma at the same time, and the serum protein concentration remained unchanged, though the total circulating protein increased.

At the end of seventy-two hours approximately one-fourth of the plasma protein was protein which had been added to the plasma after venesection. Loss of blood acted as a physiologic stimulus for the production of normal protein, and the addition of the new protein did not change the proportions of the albumin and the various globulin fractions.

When physiologic solution of sodium chloride was given intravenously immediately after hemorrhage, it was not retained in the blood stream in sufficient quantity to restore the plasma volume to normal.

After hemorrhage the blood volume was not restored to normal until new plasma protein had been added to the circulation.

Hematocrit readings in these experiments accurately reflected the direction of a change in plasma volume.

NEPHROSIS: Acacia in the Treatment of the Nephrotic Syndrome, Goudsmit, A., Binger, M. W., and Keith, N. M. Arch. Int. Med. 68: 513, 1941.

Intravenous injection of acacia into 4 patients who had the nephrotic type of edema was followed by marked increases in urinary excretion of water and of chloride (expressed in terms of the sodium salt). This increased excretion of sodium chloride and of water brings about a reversal of conditions which is significant and beneficial, considering the excretion by untreated patients. Neither increases in the volume of the circulating blood nor changes of colloid osmotic pressure appear to account for this change in renal function. Experiments on animals have also demonstrated this increased excretion of chloride after intravenous administration of acacia. It is suggested that an analogous effect might well be responsible for the diuretic response of these patients.

FLUIDS, BODY, Suggested Modification of Mandelbaum's Method of Examining, for Cells, Tannhauser, S. Arch. Path. 32: 450, 1941.

The fluid (pleural or ascitic) is collected with addition of an appropriate amount of an anticoagulant (sodium citrate or potassium or sodium oxalate). After centrifuging the mixture in a large tube with a flat round bottom, a suitable amount of oxalated or citrated plasma is added; double the quantity of the remaining centrifugate has been found appropriate. If, for instance, an oxalated plasma, obtained by adding 0.4 c.c. of 4 per cent potassium oxalate to each 10 c.c. of blood, is used, 10 drops of a 0.5 per cent solution of calcium chloride for each cubic centimeter of plasma will induce clotting. It is important to add foreign plasma and not to rely on the clotting properties of the body fluid, since often this will not clot, owing to previous spontaneous defibrinization. The centrifugate is thoroughly

mixed with the plasma, and calcium chloride is added. In a short time clotting starts and encloses all cells present in the centrifugate. After retraction the clot is transferred to a 10 per cent solution of formaldehyde or Zenker's fluid for fixation, and its further treatment is that of any other specimen, with the fibrin of the clot holding the cells together in a satisfactory way.

When oxalated or citrated plasma is not available, a few centimeters of freshly obtained venous blood may also be used to advantage.

The particles of malignant growth stand out well from the blood clot. In case an examination of the cellular content of the fluid is desired besides examination for cells or particles of malignant growth, that has to be done on a separate smear before addition of the blood.

This modification of the method of Mandelbaum may also be used when examination of sputum for malignant cells is to be made and paraffin embedding of the whole sputum is desired. The procedure then differs somewhat from that described:

In order to prevent disintegration of the cells by the action of the always present bacteria, the sputum is directly collected in a 10 per cent solution of formaldehyde. Usually the mucous sputum balls are dissolved or precipitated in small fragments by the formaldehyde (except when the sputum is highly albuminous; it then is more coherent after fixation with a solution of formaldehyde alone). After fixation of the sputum for twenty-four hours, the particles are centrifuged and washed twice with distilled water; a suitable amount of plasma with calcium chloride solution is then added. The resulting clot is again transferred to a solution of formaldehyde or Zenker's solution for fixation, washed and dehydrated in the graduated alcohols as already described.

FORENSIC MEDICINE: Significance of Dextrose and Non Dextrose Reducing Substances in Postmortem Blood, Hill, E. V. Arch. Path. 32: 452, 1941.

Post-mortem samples of blood for determinations of dextrose should be removed from the left side of the heart if significant errors due to the post-mortem diffusion of dextrose from the liver to the right side of the heart are to be avoided. The dextrose responsible for the post-mortem rise in dextrose on the right side of the heart is liberated by glycogenolysis occurring in the liver. Fasting animals or cadavers presenting marked hepatic damage do not show this post-mortem rise in dextrose.

Glycolysis occurring after death causes a progressive lowering of the dextrose content of the heart's blood. Intravascular and in vitro glycolysis occur at approximately the same rate and are not influenced by clotting of the blood.

The rate of glycolysis was studied in vitro at various temperatures, and the temperature coefficient of the reaction was determined.

The dextrose and nondextrose reducing substances were determined in 73 medicolegal and hospital cases. Significant quantities of residual dextrose were present in the majority of cases of asphyxia, shock, acute coronary closure, rapidly developing anoxemia, increasing intracranial pressure, and fluoride poisoning, indicating that agonal hyperglycemia was present.

For significant results in cases in which hypoglycemia is suspected, specimens of blood for analysis should be taken within two hours after death.

CLINICAL AND EXPERIMENTAL

PRODUCTION OF PYROGEN BY SOME BACTERIA*

CO TUI, M.D., AND M. H. SCHRIFT, M.S., NEW YORK, N. Y.

HISTORICAL REVIEW

IN 1911 Hort and Penfold showed that the intravenous injection of freshly distilled water caused no symptoms in animals and in men, while the intravenous injection of the same water, after it had been incubated in unsterile vessels, caused a febrile reaction. Since the fever-producing principle was still present after the water had been passed through a Berkefeld filter, these authors postulated that this principle, provisionally called pyrogen, was a product associated with bacteria but was not a part of the bacterial bodies themselves.

In 1923 Siebert, studying the febrile reaction following the intravenous administration of distilled water in rabbits, confirmed the findings of Hort and Penfold, and showed conclusively the bacterial origin of pyrogen. With Bourn, Siebert in 1925 studied 25 strains of bacteria isolated from distilled waters and reported that those responsible for the production of mild fevers were related to the Jordan group X of river-water bacteria, those producing severe fevers to group XI, while the nonpyrogenic bacteria fell into group XIII, which were chromogenic. According to a more recent classification (Bergey, 1930), these organisms would all be in the family *Bacteriaceae*, with the strong and mild pyrogen producers belonging to the genera *Achromobacter* and *Escherichia*, and the nonpyrogenic organisms to several genera of the tribe *Chromobacterieae*.

Banks in 1934 reported that *Pseudomonas ureae* and *scissa*, two species of the genus *Pseudomonas* which he isolated from surface waters, were pyrogenic. Apparently not familiar with the more extensive bacteriologic work of Bourn and Siebert, he stated categorically that these two organisms were specific pro-

*From the Laboratory of Experimental Surgery, New York University College of Medicine.

Received for publication, January 16, 1941.

ducers of pyrogen, and that pathogens, as represented by *Staphylococcus aureus*, and nonpathogens, as represented by *Bacillus subtilis*, were productive of a delayed febrile response and, therefore, could not be classified as pyrogen producers. Banks's work, while containing many conclusions now found untenable, added one more genus to those found by Bourn and Siebert as pyrogen producers and refuted Siebert's impression that pyrogenicity was associated with achromogenicity.

Thus far the study of pyrogen production has been confined to the bacteria found in waters. However, the striking parallelism between the symptomatology of a pyrogenic reaction from "reactive" waters, and that caused by the intravenous injection of typhoid vaccine, or of acacia and sera made "reactive" by the implantation of other strains of bacteria, indicates the close kinship of these fever-producing principles. This kinship is made still closer by the similarity of their filtration characteristics as shown by Co Tui, Benaglia, Ruggiero, and Yates.

It thus appears that pyrogen production may be much more widespread than was first embraced in the concepts of Siebert and Banks. The present work is an attempt to determine how universal this phenomenon is.

EXPERIMENTAL PROCEDURE

Eighteen strains of microorganisms belonging to different genera, tribes, and families were investigated. They were prepared for tests in three different ways.

In the first series 12 bacterial strains grown in initially pyrogen-free broths were used. The cultures were incubated for forty-eight hours at their particular optimum temperatures, and then centrifuged at 4,000 r.p.m. for forty-five minutes in an angle centrifuge. The supernatant fluid was filtered through a Berkefeld "W" filter, and the sterile filtrate was tested. These tests may be considered primary tests, since the immediate media in which the organisms grew were used.

The second series consisted of bacteria which were more convenient to grow on slants or in Kolle flasks. The colonies were washed out with a few cubic centimeters of pyrogen-free physiologic saline solution containing 0.4 per cent phenol, inactivated for forty-five minutes by heat. The suspension was filtered as in the case of broth cultures, and the filtrate was tested. These tests may likewise be considered primary tests, since whatever pyrogen was present in the colonies would presumably go into solution in the suspending media. Four organisms were tested in this way.

The third series consisted of nine organisms tested in the form of vaccine made with pyrogen-free water. The first three were highly pathogenic organisms; namely, *Vibrio comma*, *Neisseria intracellularis*, and *Pasteurella pestis*. These organisms were prepared in sets of two; one set by a biological firm and the other by the bacteriologic department of the university. The other six organisms in this series had been tested in series one, so that the tests in this case serve merely as a check. All these vaccines were passed through a Berkefeld filter, as in the case of the other two series and the cell-free filtrate used. The

tests in this series may be thought of as secondary tests, since the media tested were not in immediate contact with the living bacteria. While a positive finding may be considered significant, a negative finding may only mean that the pyrogen produced may be so slight as to be lost in the process of making the vaccines.

A positive pyrogenic reaction in the dog, as reported in our previous communications, consists of a leucopenia thirty to forty-five minutes after the intravenous injection of the pyrogenic material; a rise of temperature which begins to be perceptible thirty minutes after injection, reaching a peak in from two to four hours and returning to normal in four or five hours. In mildly severe reactions there are prostration and gastrointestinal symptoms, such as vomiting and diarrhea, both of which may contain blood. These symptoms are comparable to those in men.

The dog is used throughout this work not only because of the consistency of its temperature curve, but also because the constancy of the leucopenia and the frequent appearance of the secondary symptoms of prostration and gastrointestinal disturbances serve as an added check.

That this pyrogenic reaction is not due to nucleic acid is shown in three experiments in which the intravenous injection of 1, 3, and 5 mg. of pure nucleic acid, prepared by Dr. P. A. Levene, into each of three dogs failed to provoke a similar response.

DISCUSSION OF RESULTS

Table I summarizes the results of this investigation. The first four organisms have not been classified as to either species or genera, but belong to the family of the Bacteriaceae of the tribes Achromobacterieae and Chromobacterieae. W14B and W14C were isolated from well water, and 31y and 2WS from pond water. Their best growth was obtained at 20° C. They were gram-negative bacilli, varying in shape from minute bacillary forms in the case of W14B to a large coccoid form in the case of W14C. 31y was a small bacillus exhibiting chromogenic properties and imparting to the broth and agar preparations a light yellow color. 2WS was the largest bacillus of the group and often grew in long chains.

All these four organisms were included here to show the similarity of the pyrogenic reaction elicited by the injection of their products and that elicited by the injection of the products of microorganisms of other groups.

Each item listed in Table I has been selected from a series of at least five experiments as the one best representative of that series.

A study of the table shows a number of interesting facts. The first 13 organisms listed in Table I are all pyrogen producers, 9 of them not being members of the river-water group. Four of these, namely, *E. typhi*, *Streptococcus pyogenes*, *Vibrio comma*, and *N. intracellularis* are pathogens. Two others, *E. coli* and *Staphylococcus aureus*, are facultative saprophytes. It will also be seen that it takes different amounts of the broth filtrate to produce a reaction of an intensity similar to the range of reactions common to the pyrogen producers in the table, the dose ranging from 1 c.c. to 15 c.c. While this may be interpreted to mean that some microorganisms are better pyrogen producers

TABLE I

ORGANISM	FILTRATE TESTED	AMOUNT USED (C.C.)	CONC. PER C.C. VACCINE IN BILLIONS	DOG WEIGHT (KG.)	W.B.C. DROP (THOUSANDS)	CHANGES IN TEMP. (° F.)	SYMPTOMS

than others, yet it could also mean that the rates of rapidity of their proliferation may be different. Unless bacterial counts are made of the cultures, this point cannot be settled.

In the case of the vaccines, however, where some quantitation has been used, the indication that some bacteria are better pyrogen producers than others is stronger. Thus of the 8 organisms tested in the vaccine form, it takes only three billion cells of *V. comma* to produce a cell-free vaccine filtrate which causes a temperature rise of 4.2° F., ten billion in the case of *E. coli* to produce a rise of 3.1° F., and ten billion of *E. typhi* to produce a rise of 2.8° F., while it takes 300 billion of 2WS to produce a rise of 3.5° F. These figures would seem to indicate that *V. comma* is the most efficient producer of pyrogen among these strains with *E. coli*, *E. typhi*, *N. intracellularis*, and W14C second and 2WS the least.

Of practical importance from the viewpoint of air contamination in the production of pyrogen in the preparation of medicaments and other chemical solutions is that *Proteus vulgaris* and *B. subtilis* are pyrogen producers.

It is also of particular significance that wild yeast produces pyrogen. This opens the field for further experimentation in group of yeast and molds.

The last five microorganisms in the table; namely, *C. diphtheriae*, *Pasteurella pestis*, *Pasteurella cuniculicida*, *M. tuberculosis* and the *gonorrhoeae* were according to these tests nonpyrogenic. All these were subjected to primary tests, except *Pasteurella pestis*, which was tested only in the vaccine form, using an amount equivalent to 25 billion cells. *Pasteurella pestis* is thus at best a weak pyrogen producer if at all. In all these negative tests it is interesting to note

TABLE II

that the white blood cell count did not undergo any substantial change except in the case of the *N. gonorrhoeae* test in which there was a suggestive fall.

It is clear from these studies that the matter of pyrogen production is not associated with pathogenicity as first postulated by Banks or with chromogenicity as postulated by Siebert (1923), or with the property of taking or rejecting the Gram stain as suggested by Cecil.

In Table II are compiled all the bacteria tested for pyrogen production from data furnished in the work of Siebert, of Banks, and in our present work. It will be seen that the greatest number tested have been selected from the order of the Eubacteriales of the class Schizomycetes, with particular emphasis on the family Bacteriaceae. In addition to the three tribes of the family Bacteriaceae that Siebert found pyrogenic and to the one genus of the tribe Chromobacterieae by Banks, the present work has added four families of the order Eubacteriales, one family of the order Actinomycetales, embracing a total of eleven known genera and thirteen known species.

SUMMARY

In a study of pyrogen production by representatives of different orders, families, genera, and species of bacteria, it was found that this phenomenon is a more widespread one than has hitherto been envisaged. It is not confined to any one group, but occurs in a number of different groups. Nor is it associated with nucleic acid, with pathogenicity, chromogenicity, nor with the property of taking the Gram stain. The production of pyrogen by a member of the yeast group suggests that even higher forms than bacteria may possess this property of pyrogen production. How pyrogen is related to the various toxic substances isolated by various workers from different bacteria remains to be studied. This statement implies that chemically and immunologically pyrogen is still an unknown entity. It is interesting to note that in this work a physiologic criterion has been used for the study of a bacterial product, a criterion distinct from those in use heretofore, namely, death or the production of antibodies in experimental animals. It is quite conceivable that there may be some bacterial products which are neither lethal nor antigenic and are, nevertheless, physiologically potent.

We wish to acknowledge our indebtedness for the aid in the preparation of experimental material given by Dr. Julius A. Klosterman, of the Department of Bacteriology, New York University, College of Medicine, by the Baxter Laboratories of Glenview, Ill., and the Sharp & Dohme Company, Philadelphia, Pa. To the late Dr. P. A. Levene we are indebted for the preparation of pure nucleic acid.

INTESTINAL VASCULAR SCLEROSIS*

JOSEPH FELSEN, M.D., NEW YORK, N. Y.

INTESTINAL vascular sclerosis is a condition of the mesenteric blood vessels usually associated with old age and often accompanied by disordered bowel function.

Pathology.—Narrowing of the extramural and intramural mesenteric vessels is part of a more generalized systemic condition of degenerative vascular disease associated with senescence. From the pathologic viewpoint these changes consist chiefly of disruption or disappearance of the elastic lamina, fatty degeneration with subintimal proliferation, calcific deposition, and atrophy of the media. The end result is a narrowed, rigid vessel, which is unresponsive to the ever-changing circulatory requirements of the organs supplied. The most advanced disease is generally seen in the larger arteries, where actual widening of the lumen may occur. This is essentially due to weakening of the wall from degeneration of the media and elastica. In the smaller arteries, however, such as those seen in the intestinal submucosa, the most common change noted is a subintimal proliferation of connective tissue. This deposition of connective tissue is often accompanied by thickening of the elastica, both representing an adaptive overgrowth to bolster the overlying weakened media. Occasionally this process occurs in young people following systemic infections, but its prevalence in the older age groups appears to be associated with the biologic process of aging. Complete obliteration of the intramural intestinal vessels sometimes occurs and can be readily detected at necropsy by subjecting the opened bowel to transillumination.¹ They stand out as straight, tapering, white, bloodless, threadlike filaments. By careful section of selected areas one can often trace successive stages in the same vessel. In some instances narrow clefts form in the fibrous tissue which obliterates the vessel lumen. These clefts are lined by endothelial cells; they often contain erythrocytes and represent an attempt at recanalization. In this manner it appears quite possible that a fair blood supply may be maintained, though it is probably inadequate as compared with that carried by the normally patent vessel.

Clinical Aspects.—In mild, moderate, or recanalized forms of intestinal vascular sclerosis few or no symptoms may be present. In patients with the more advanced type of disease the chief clinical symptoms and signs are abdominal distention, constipation, indigestion, and abdominal cramps after eating. One or all may be present, depending upon the degree of vascular narrowing. They are most frequently encountered in the sixth and later decades of life, but they may be present earlier. The adage "a man is as old as his

*From the Department of Pathology and Research, the Bronx Hospital, New York.
Received for publication, January 20, 1941

arteries" is applicable to the intestinal vessels. "Senescence" is a relative term, however, as Boas² has recently pointed out, varying considerably in different persons. Thus, relatively young people may have intestinal vascular sclerosis, and some old people are comparatively free of it (Humphrey,³ Groddeck⁴). The former generally exhibit concomitant changes in the glomerular tufts and larger renal vessels with persistent hypertension, either because of a glomerular nephritis complicating some infectious disease or as the late phase of essential hypertension with arteriolosclerosis. In older people, however, hypertension is not invariably present any more than in coronary sclerosis, or sclerosis of the cerebral arteries. Intestinal vascular sclerosis is essentially a focal manifestation of generalized arteriosclerosis. The thought has often occurred to us that the epigastric and other abdominal discomfort in coronary disease is often due to mesenteric sclerosis. The symptoms of which patients with mesenteric sclerosis complain are often regarded as being on a purely functional basis. This, however, is not the case, as can be shown by careful general physical examination and sigmoidoscopy. The changes noted by the latter method are distinctive and readily elicited by examination of the submucosal intestinal vessels. During life, with blood coursing through the vascular arterial branches, their relative thickness, elasticity, and general contour can be determined with the aid of a telescopic device and green color filter⁵ (Wrattan X). Normally, the submucosal vessels can be seen as graceful, delicate, long, red, sinuous undulations, gradually tapering to their tips. Their elasticity can be determined to some extent by means of intermittent suction applied through the inflation tube of the sigmoidoscope. In this manner a transient period of negative pressure is created. Normal vessels, alternately redden and pale, correspond to the phases of negative and positive pressure. With advancing sclerosis and narrowing of the lumen the arteries become thicker, the undulations abrupt, tortuous, or corkscrew, and alternate suction and release produce no appreciable reddening and paling of the vessels. During the late or obliterative stage the vessels pursue a short straight course, terminating rather abruptly in white bloodless cords which do not respond to suction. Examination of the eye grounds is suggested as a supplementary procedure to sigmoidoscopy, for the retinal vessels parallel the intramural intestinal branches both as to size and extent of pathology.

The mechanism underlying the symptomatology in intestinal vascular sclerosis appears to be a transient or permanent ischemia with relative anoxemia. The bowel is a hollow muscular organ, with an exceedingly rich blood supply that must be adequately maintained for effective contractility and functioning of the digestive glands. Interference with the blood and oxygen requirements of the musculature produces spasm (i.e., muscle cramp) and later, atony. Barker⁶ states that in case histories of 260 patients over 60 years of age, digestive symptoms were second highest in frequency. While many factors must be considered, such as inadequate mastication, there still remains a large group of persons whose symptomatology can only be explained by some factor incident to the aging process. Patients will often state that small amounts of easily digested food are better tolerated than large meals, an ob-

servation that many of our keen predecessors put to practical use in the treatment of elderly patients with digestive complaints. The reason is obvious, since easily digested foods in small amounts require less work on the part of the intestine for their assimilation than bulky or indigestible foods. The impaired blood supply under these circumstances may be adequate because the digestive requirements have been adapted to the functional capacity of the bowel.

Fig. 1.—Arteriosclerosis. Mesenteric vessels thickened tortuous, or partially obliterated. Corresponds in individual cases to appearance of retinal vessels.

With advancing years, as the vascular changes progress, the intestinal musculature tends to lose its tone. This is particularly true in the colon where gas, which is normally present, is not passed readily and tends to accumulate with increasing atony of the wall, thus perpetuating a vicious cycle. The chief signs of intestinal atony are distention and constipation. In this connection it may be of interest to recall the relationship of distention to impaired gas diffusion through the intestinal wall. Normally, as pointed out by McIver, Redfield, Benedict,⁷ and others, the intestinal wall serves as a semipermeable membrane, permitting diffusion of gases in either direction, i.e., from the intestinal lumen to the blood, or vice versa. Any interference in the free passage of gases may lead to flatulence (Dunn and Thompson).⁸ Alvarez,⁹ Kato,¹⁰ Kader,¹¹ Schoen,¹² and others regard impaired circulation in the mesenteric vessels as one of the prime factors in the production of distention. Schoen stresses, in addition, the lowering in tone of the intestinal muscularis. It is my impression that both factors are closely related to intestinal vascular sclerosis and are often the result of it. In rare instances extreme sclerosis of the mesenteric vessels may result in rupture, i.e., abdominal apoplexy. This subject has been recently reviewed by Crile and Newell,¹³ who report ten cases from the literature in addition to their own. Sometimes complete occlusion of a main mesenteric arterial branch occurs with gangrene of the part of the intestine supplied. Here the process usually consists of a superimposed thrombosis in a markedly narrowed lumen.

The frequent occurrence of flatulence in patients with hypertension is well recognized, Kantor and Marks¹¹ reporting an incidence of over 50 per cent. The association of intestinal vascular sclerosis with long-standing hypertension is, in our experience, quite constant. In reviewing 1,000 necropsies at the Bronx Hospital from the standpoint of concomitant intestinal vascular sclerosis and generalized arteriosclerosis in the same person, agreement was found in all instances where advanced changes were present in the larger vessels. It may be stated that all intestinal necropsy specimens were viewed by means of the transilluminator.

Fig. 2.—Intestinal transparencies. 1, Normal intramural vascularization. Note long, delicate, sinuous undulations with gradual tapering to finest branches which anastomose freely with adjacent vessels. 2, Proliferative phase. Vessels are thickened and tortuous. 3, Obliterative phase. Vessels are straightened and rigid with obliterated terminal arborizations. 2 and 3 are from Case 2 (No. 9048).

Interference with diffusion of gases may be due to a thickened intima or impaired circulation of blood in the intestinal arterioles. In cirrhosis of the liver or failure of the cardiac musculature without arteriolar sclerosis, the fault may be entirely on the venous side.

CASE REPORTS

Group A. Cases illustrating association of intestinal vascular sclerosis and arteriosclerosis elsewhere in the body.

CASE 1.—Hospital No. 61437. Pathology No. 8675. Male, aged 45 years, was admitted on Dec. 5, 1935, with a clinical diagnosis of arteriosclerosis, coronary sclerosis, and coronary thrombosis. The blood pressure was 100 mm. systolic and 80 mm. diastolic. A complete history was unobtainable. Death occurred on the same day. At necropsy the relevant findings were an old thrombosis of the left coronary artery, a recent thrombosis of the right coronary artery, with areas of myomalacia. The entire aorta was the seat of

large atheromatous patches and ulceration extending into the common and external iliac branches. The intramural mesenteric arborizations revealed marked tortuosity and thickening. There was marked coronary sclerosis.

CASE 2.—Hospital No. 59727. Pathology No. 9048. Male, aged 60 years, was admitted on Feb. 13, 1936, and died within a few hours. During a previous admission (Oct., 1935) clinical and electrocardiographic examinations (Dr. Capp) revealed coronary sclerosis with myocardial fibrosis. At necropsy, mural thrombi were present at the apex of the heart and in the right auricle. Both coronary vessels were calcified, and a fresh thrombus was present in the right circumflex branch. An old thrombus occluded the left descending coronary artery 2.5 cm. from its origin. The aorta and other large vessels were markedly sclerotic. There was marked tortuosity and thickening of the intramural vascular arborizations with straightening and obliteration of many terminal branches. There was advanced arteriosclerotic renal disease.

CASE 3.—Hospital No. 74062. Pathology No. 11465. Female, aged 77 years, was admitted on Feb. 8, 1937. The patient was known to have had a mild form of diabetes for fifteen years. Some redness, swelling, and tenderness were present on the little toe of the right foot. There was marked peripheral vascular sclerosis. Oscillometric readings at the ankle and above the popliteal space revealed definite occlusive vascular disease. (Doctors Saland and Klein.) Roentgenographic examination (Dr. Snow) showed marked calcification of the vessels of the extremities. Diabetic gangrene of the right foot and lower third of the leg ensued, and the patient died following mid-thigh amputation on March 22, 1937. At necropsy marked atherosclerosis of the aorta with many calcific plaques and ulceration were noted. The aortic and mitral valve flaps were calcified. The larger arterial branches were similarly involved, particularly the coronary and basilar arteries. Typical arteriosclerotic renal disease was present. The intramural mesenteric branches revealed advanced sclerosis, with tortuous, thickened, and partly obliterated straight vessels.

Group B. Cases with intestinal vascular sclerosis, generalized arteriosclerosis, and marked intestinal clinical manifestations.

CASE 4.—Hospital No. 74413. Pathology No. 11501. Female, aged 56 years, was admitted on Feb. 19, 1937. The chief complaints were progressive constipation, epigastric discomfort, and belching. The patient was known to have had hypertension for two years. Upon admission the blood pressure was 260 mm. systolic and 135 mm. diastolic. The heart was considerably enlarged. Examination of the fundi revealed dilated veins and thin pale arteries, which were highly refractile and sclerotic. Scattered about the posterior aspect were fine yellowish exudates and a few scattered superficial hemorrhages (Dr. Goodfriend). On Feb. 23 roentgenographic examination revealed calcification of the arch of the aorta. There was loss of substance in the tufts of the index, middle, and little fingers on both sides, indicating circulatory deficiency (Dr. Snow). Oscillometric studies (Doctors Saland and Klein) revealed diminished oscillation in the vessels of both ankles, wrists, and right arm. Thermal tests indicated complete absence of reflex vasodilatation in both extremities. These findings pointed to organic obstructive arterial disease. The patient gradually developed uremia with marked nitrogenous retention and died on March 25, 1937. The relevant necropsy findings were a marked ulcerative atherosclerosis of the entire aorta and small granular arteriosclerotic kidneys. The intramural intestinal arterial arborizations were rigid, thickened, and corkscrew-shaped, with partly or completely obliterated straight terminal branches.

The following brief case reports have been selected from a group of 15 to illustrate the possibilities of accurate diagnosis of intestinal vascular sclerosis by sigmoidoscopy and the value of oxygen as a therapeutic agent.

CASE 5.—A. K., female, aged 55 years, complained of recurring attacks of abdominal cramps, constipation, distention, and a sense of epigastric pressure accompanied by labored breathing, particularly at night. Occasionally there was severe precordial pain radiating to both shoulders. Prior to the onset of these symptoms the blood pressure had been 190

mm. systolic. At the time of consultation it was 150 mm. systolic and 90 mm. diastolic. Cultural, serologic, and parasitologic studies were negative. Sigmoidoscopic and ophthalmoscopic examinations revealed marked sclerosis of the intestinal and retinal vessels. A diagnosis of coronary sclerosis and intestinal vascular sclerosis was made, both being part of a more generalized arteriosclerosis. Considerable relief of abdominal symptoms followed aspiration of the colonic gases and the use of intestinal oxygenation. Several weeks later, after being comparatively free of symptoms, there occurred an acute episode of abdominal pain and an emergency exploratory laparotomy was done at Mt. Sinai Hospital for what appeared to be an acute intestinal obstruction. No obstruction was found, though an omental adhesion in the region of the splenic flexure was present. The striking finding, however, was "a considerable degree of sclerosis in those major abdominal arteries which were seen or felt,"¹⁵

CASE 6.—F. K. G., female, aged 64 years, had recurring attacks of abdominal cramps accompanied by nausea for which she had undergone a cholecystectomy eighteen months previous, but without relief. Physical examination revealed a nervous, apprehensive woman, who exhibited evidence of cerebral arteriosclerosis and mental deterioration associated with senility. There was advanced intestinal and retinal vascular sclerosis. The blood pressure was 140 mm. systolic and 100 mm. diastolic. A diagnosis was made of mesenteric vascular sclerosis with relative anoxemia and intestinal spasm. Temporary abatement of symptoms occurred with intestinal oxygenation, but the mental condition of the patient rendered continued therapy difficult. Roentgenographic studies revealed the presence of a diaphragmatic hernia with diverticulosis (Dr. A. F. R. Andresen). There appeared to be no evidence, however, that the intestinal symptoms were due to either of these conditions. Subsequent studies were carried out at Mt. Sinai Hospital in an attempt to elicit an allergic factor, because of a history of migraine, but these were without success. Several weeks later the patient suddenly died of cerebral apoplexy. It was quite evident in this case that not only were the intestinal vessels sclerotic, but the cerebral, aortic, and peripheral blood vessels were likewise affected.

CASE 7.—B. A., female, aged 58 years, had abdominal cramps, distention, and constipation for two years, which was relieved by rest and quantitative, rather than qualitative, dietary restrictions. Repeated roentgenographic studies were essentially negative. Generalized arteriosclerosis was present with moderately advanced changes in the retinal and intestinal vessels. The condition was relieved by the use of approximately 200 c.c. of oxygen administered by rectum once daily. The patient has increased the total amount of food ingested but still eats rather sparingly by choice. The follow-up is now approximately two years, the patient having completely abandoned the use of enemas to which she was previously addicted. At the present time she has one normal bowel movement daily.

CASE 8.—P. Z., female, aged 70 years, complained of obstinate constipation for many years. For several years the patient noted blood in the bowel movements due to the presence of hemorrhoids. Epigastric and precordial distress with a sense of fullness after meals were present for three years. These symptoms were relieved by rigid restrictions in the quantity of food or by a smooth, low residue diet. There was increasing anorexia and a weight loss of 30 pounds. The essential physical findings were abdominal distention, evidence of hypovitaminosis, and generalized arteriosclerosis. The sigmoidoscopic appearance of the intramural intestinal vascular branches was typical of advanced arteriosclerosis, and similar findings were noted in the retinal vessels. The possibility of coronary sclerosis was entertained, but there was no evidence of an acute thrombosis. With intestinal oxygenation the symptoms were ameliorated with a surprising rapidity that could not be accounted for by psychic or other factors. The appetite improved, all dietary restrictions being removed, and with it the state of vitamin deficiency disappeared. Enemas and other forms of catharsis were immediately stopped, and the patient has had normal daily bowel movements, with rare exceptions, for the past five months. In this case it was felt that the oxygenation made possible the handling of large quantities of food by

the intestinal tract. That the total bulk was not an important factor is attested by the fact that the patient had been constipated before dietary restrictions were imposed by her physician.

THERAPY

The treatment of intestinal vascular sclerosis is based upon a logical consideration of the physiologic and pathologic factors involved. Our present state of knowledge does not point to any agent which can restore to normalcy the narrowed caliber of mesenteric vessels due to the degenerative changes of senescence. Our efforts must be directed toward supportive and corrective measures which will enable a permanently impaired mechanism to handle adequately the limited digestive requirements of old age.

Fig. 3.—Moderate narrowing of the lumen of a mesenteric intramural branch due to subintimal proliferation. Note that elastica is intact.

(a) *General supportive measures.* If signs of myocardial failure or hypertension are present, adequate drug therapy combined with fluid restrictions should be instituted. Supplementary post-prandial rest periods besides the usual rest requirements will prove helpful.

(b) *Dietary limitations.* The caloric requirements of sedentary old age are obviously much less than those of youth or active middle age. Nature appears to be orderly in her plans. With the vascular and other degenerative changes of senescence, there is a lessened tendency to remain physically active, and with it a diminution in the desire for food. Old people become more “picky” in their food habits and are less apt to overeat than was their custom in youth. Violation of this simple rule often brings on abdominal discomfort

so that individuals soon learn their limitations and steadfastly observe them. Simple, easily digested foods, small in total bulk, well masticated and eaten slowly, are indicated. Ordinarily three meals daily will provide sufficient caloric intake without excess bulk. If not, the same quantity can be divided over five meals. No special food restrictions are indicated, except where specific idiosyncrasy exists. If further restrictions must be made, the addition of vitamin concentrates is advisable. One "fasting" day each week will often be found beneficial, and consists in limiting the food to water, broth, milk, and fruit juices. Although lack of bulk favors constipation, adequate adjustment seems to occur particularly with the aid of intestinal oxygenation.

Fig. 4.—Extreme stenosis of lumen of a submucosal vessel. Note marked subintimal proliferation and several breaks in continuity of the elastica.

(c) *Intestinal aspiration.* By intermittent suction through the sigmoidoscope, distention can be relieved. It also appears to serve as a gentle internal massage to the bowel wall and tends to improve the tone of the musculature. This method is only employed at the beginning of therapy and is later completely replaced by intestinal oxygenation. It is essentially an office procedure carried out under direct vision. Relief is prompt and generally lasts for about twenty-four hours.

(d) *Intestinal oxygenation.* Intestinal oxygenation and the rationale of its employment have been described elsewhere.¹⁶ Normally the large bowel is free or almost free of oxygen. It has been shown that following intestinal oxygenation, the gas is absorbed into and through the wall, increasing the oxygen tension within the blood plasma and the peritoneal cavity.¹⁷ Conversely, the inhalation of oxygen increases the tension within the bowel lumen through the indirect hematogenous route. The bowel wall appears to serve as a semipermeable membrane, diffusion of the oxygen taking place either from the bowel lumen to the plasma or in the reverse direction. Man literally breathes through his intestine. The direct instillation of oxygen into the bowel lumen has been found most effective. It appears to improve the muscle tone and the elasticity of the wall. One of the most striking effects is the relief of constipation. Patients habituated to the use of enemas, who perhaps could

not move their bowels otherwise for three or four days, soon have daily formed bowel movements. The same effect is often noted in young patients. We have been able to demonstrate this effect in some patients suffering from constipation over a period of fifteen years without changing any other factor except the withdrawal of all cathartics and enemas. It is hardly conceivable that the presence of 200 c.c. of oxygen in a colon with a capacity of 2 to 3 liters has any direct mechanical effect by distention of the bowel wall, particularly since the gas is given very slowly. Another interesting observation in connection with the use of oxygen is the rapid disappearance of foul odor from the stool.

Fig. 5.—Apparatus for intestinal oxygenation, including small warming coil for immersion in basin of hot water or placing upon electric pad. A No. 16 soft rubber catheter is inserted into the rectum.

The oxygen dosage usually employed is approximately 200 c.c., one to three times daily. The apparatus pictured is set up in the bathroom, and the distal 3 or 4 inches of a No. 16 soft rubber catheter lubricated with K-Y jelly is inserted into the rectum. Administered at the rate of 90 bubbles per minute for ten minutes, it will deliver approximately 200 c.c. of oxygen at room temperature. Any similar device may be used. The gas is usually given with the patient in the upright position on the toilet seat, but in debilitated patients it may be administered in the recumbent posture. After proper instruction in the use of intestinal oxygenation, the patient is permitted to continue treatment at home. In some instances the dosage can eventually be cut down after one or two months or even discontinued except for periodic short intervals. During the ten years that intestinal oxygenation has been employed, no untoward result has been reported. In cases where the rectal route is not feasible, the oxygen may be administered by inhalation, though larger amounts are required to relieve intestinal atony.

In closing, it may be stated that no broad generalizations with regard to the therapeutic effects of oxygen are intended. Our experience has been sufficiently large, however, to warrant a rather conservative report so that others may be encouraged to judge of its usefulness.

SUMMARY

Intestinal vascular sclerosis is essentially a disease of old age. The chief symptoms are distention, constipation, indigestion, and abdominal cramps. Therapy consists of cardiovascular supportive measures, an easily assimilated diet, intestinal aspiration, and intestinal oxygenation.

I wish to acknowledge gratefully the assistance of Dr. I. Rothstein and Dr. W. H. Kastl in reviewing 1,000 necropsy protocols.

MONOETHANOLAMINE (MONOLATE)

AN EXPERIMENT ON ITS ANTIGENIC PROPERTIES

STANLEY R. TRUMAN, M.D., OAKLAND, CALIF.

SINCE the beginning of treatment of varicose veins by injection, there has been a constant search for a more satisfactory sclerosing agent. At the present time sodium morrhuate is the most widely used solution. However, there are numerous reports of allergic reactions to sodium morrhuate, and several deaths, apparently due to allergic reactions, have been reported. These reactions could be expected because sodium morrhuate is made of the sodium salts of the fatty acids of cod-liver oil and is not protein free.

Recently, there has been marketed a solution of monoethanolamine oleate^{*} which closely resembles sodium morrhuate in clinical use and results. Because this solution contains no protein, it was hoped that it would be free of the annoying and occasionally disastrous reactions of sodium morrhuate. A limited clinical trial has shown the material to be very satisfactory. During the period of clinical trial, a death was reported by Shelley,¹ which he ascribed to an allergic reaction to the injection of monolate. Recently, Golden and Heyerdale² have reported a case of sensitivity to both monolate and sodium morrhuate in the same individual. Although no other reports of allergic reactions or sensitivity to monolate have appeared in the literature, it was thought that a laboratory test of the antigenic properties of monolate would be desirable. The following experiments were then performed with a comparison of the antigenic action of 5 per cent sodium morrhuate and monolate.

REPORT OF EXPERIMENTS

Experiment 1. Each of three guinea pigs was injected intraperitoneally with 1 c.c. of 5 per cent sodium morrhuate. Three weeks later each was reinjected with 5 per cent sodium morrhuate. All showed a typical anaphylactic reaction. Two sneezed and became apprehensive; their hair raised, they had a slight convulsion, and recovered. The third had a similar reaction, with a more severe convulsion, and died.

Experiment 2. Each of 12 guinea pigs was injected intraperitoneally with 0.5 c.c. to 1.0 c.c. of monolate, depending on the size of the pig. Three weeks later each was given an intraperitoneal dose of 1.0 to 3.0 c.c. of monolate. There was no reaction in any guinea pig.

Experiment 3. Two cubic centimeters of monolate were injected into the ear vein of a rabbit. Three weeks later 2 c.c. of monolate again were injected intravenously. There was no reaction.

^{*}Monolate.

Received for publication, January 20, 1941.

Experiment 4. Equal doses of 5 per cent sodium morrhuate and monolate were injected subcutaneously into a rabbit's ears. The size, intensity, and duration of the inflammatory reactions were practically identical.

Experiment 5. (a) Monolate gives a negative reaction to protein by the Greenberg method for total protein. (b) Monolate gives a positive biuret test. This is due to the monoethanolamine, and does not indicate the presence of protein. (c) Micro-Kjeldahl test is also positive. This is due to the presence of nitrogen in monoethanolamine, in the form of an amino group, and again does not indicate the presence of protein.

DISCUSSION

The results of this experiment were anticipated on the basis of the chemical compositions of the sodium morrhuate and the monolate. Sodium morrhuate is derived from cod-liver oil, and contains some protein, to which guinea pigs are readily sensitized and show a typical anaphylactic reaction. Monolate contains no protein and apparently will not sensitize guinea pigs. Although it is not possible on the basis of this small number of animals to make a final statement about the antigenic properties of monolate, it is encouraging to find that it is not a sensitizing antigen for any of this group of guinea pigs.

The similar inflammatory reaction produced on a rabbit's ear would reaffirm the clinical impression of a similarity of the sclerosing activity of the 5 per cent sodium morrhuate and monolate. Actually, in practice the monolate seems slightly more potent than sodium morrhuate, and to get a similar reaction, about two-thirds as much monolate as 5 per cent sodium morrhuate can be used.

Of course, no light has been thrown on the problem of drug sensitivity, and anyone who undertakes to give a large number of injections of any drug will sooner or later run across some person who is sensitive to that drug. At the present time no means of predicting such sensitivity has been determined. It has been my custom to give a very small injection of 0.2 c.c. to 0.3 c.c. at the time of the first injection, hoping to measure the patient's reactions to the injection and to the drug. This may be helpful.

CONCLUSIONS

No antigenic activity could be demonstrated experimentally in monolate. If it has any antigenic property, it is certainly much less antigenic than 5 per cent sodium morrhuate, which it closely resembles in application and results. Monolate is, therefore, a more satisfactory agent for use in the injection treatment of varicose veins.

I wish to express my thanks to Dr. Paul Micheal for performing the laboratory test and for the use of his laboratory facilities for the animal experimentation.

MULTIPLE PRIMARY MALIGNANT LESIONS*

JOHN L. TULLIS, M.D., NEW YORK, N. Y.

MANY reports of multiple primary malignant lesions in the same persons have appeared in the literature since Billroth published the first case in 1869. The first American author to become interested in the problem was Major who, in 1918, reviewed the literature, which was chiefly contributed by German authors. Subsequently Owen (1921), Ophüls (1926), Hanlon (1931), Warren and Gates (1932), Hurt and Broders (1933), Schreiner and Wehr (1934), Bugher (1934), Burke (1936), Austin (1938), Kirshbaum and Shively (1938), and Stalker and others (1939) have contributed materially to the American literature by publishing large series of cases. In addition, many authors have contributed isolated cases or small series of cases. The summaries of the larger series of cases may be found in Tables I, II, and III where the several series are broken down into small groups because of variations in methods of diagnosis and, particularly in the autopsied and surgical cases, because of the variation in sex incidence and the types of lesions encountered. The Bellevue cases conform in general with those of the quoted autopsy cases.

The Bellevue Hospital material was selected from 6,836 consecutive autopsies performed in the four divisions of the hospital during the past eight years. In 1,044, or 15.2 per cent, of these autopsies malignant lesions were diagnosed, and in 21 of the 1,044 autopsies, or 2.0 per cent, more than one independent malignant lesion was diagnosed. The 21 cases here presented were selected after a review of the autopsy protocols, the microscopic sections, and the clinical histories. The cases are not limited to carcinomas, but include all types of malignant lesions.

The microscopic sections meet the following criteria:

- a. Each lesion possesses generally recognized malignant characteristics.
- b. Each lesion has the histologic pattern commonly associated with malignant lesions arising from the tissue or organ in question.
- c. Each lesion is a distinct entity, metastases having been considered and ruled out in so far as possible in each instance. These criteria closely follow those established by Warren and Gates, and, like theirs, exclude an additional criterion, namely, that each tumor must produce its own metastases, which was advocated by Billroth but which has since been generally discarded.

The clinical histories were studied with a view to establishing the relationship of the duration of the individual lesions and collecting data relative to the familial tendency to malignant diseases. Investigation along both these

Ward	1,773	94	5.3	--	55:39
Schreiner and Wehr	11,212	307	2.7	--	--

lines was disappointing. Frequently, unless one of the lesions was on the body surface, ante-mortem diagnosis of the second lesion was not made. As for the familial tendency, in only 3 cases (Nos. 1, 17, 19), or 14 per cent, was there a positive family history of cancer. This is slightly below the figures of 15 to 30 per cent usually reported. However, in one case the causes of death of the patient's family were unknown to him, and in 2 others this information was not obtained before the patients' death. If these 3 cases are subtracted from the total, the percentage of positives becomes 16.6. Even this is believed to be an understatement, since the typical Bellevue patient is drawn from a large city with a large immigrant population. Often he has an imperfect knowledge of English; more often he has lost contact with his family in the fatherland.

Realizing that errors of omission are as unfortunate as errors of commission, a conscious effort to avoid both was made. It was felt that lesions with a known tendency to multicentric origin, such as multiple parenchymal cell carcinomas

of the liver, and lesions of possible malignant origin, which are not yet universally accepted as such, including the leucemias and Hodgkin's disease, should be excluded from this series. Also two cases of bilateral hypernephromas of identical histologic pattern, where it was impossible to rule out the possibility of one being a metastasis from the other, and one case of bilateral carcinomas of the ovaries, where similar conditions prevailed, were not included. However, one case of bilateral carcinomas of the female breasts was included because the one had been surgically removed four years before the appearance of the other, and the two were of different histologic pattern.

TABLE IV

21	M	74	Adenocarcinoma	Stomach	0	Adenocarcinoma of polyp	Stomach	0
						Adenocarcinoma of polyp	Stomach	0

The cases are listed as a group in Table IV. There are 21 cases, representing 44 lesions, of which 3 are sarcomas and 41 carcinomas. Tables V, VI, VII, and VIII show the organs or organ systems most frequently involved.

The gastrointestinal system is most frequently involved. Twelve cases (57 per cent), representing 20 lesions, are listed under this category. Eight of these 12 cases show 11 lesions in the stomach. Only 2 lesions involve the skin pri-

marily, although 6 lesions arise from stratified squamous epithelium. This distribution is in accord with that in other autopsy series, but is in complete disagreement with the distribution in the surgical and clinically observed cases. In the surgical and clinical series stress is laid on the predominance of skin neoplasms among multiple malignant lesions. Fifty-eight of the 152 lesions among 71 surgical cases reported by Hurt and Broders originated in the skin. Thirty-five of the 113 cases reported by Stalker and associates involved only the skin. Ward, working in England, who reported only rodent ulcers, states that 5.3 per cent are multiple. Since these lesions are by virtue of their location discovered readily and early, they are frequently successfully treated before the patients come to autopsy. If there is a change of hospitals in the interim, the foreign clinical records may be lost to the pathologist.

TABLE V

CASES IN WHICH AT LEAST ONE OF THE LESIONS IS PRIMARY IN THE GASTROINTESTINAL TRACT

CASE NO.	SEX	AGE	LESION	ORGAN	LESION	ORGAN
4	M	68	Spindle-cell sarcoma	Stomach	Squamous-cell epithelioma	Esophagus
5	M	34	Adenocarcinoma	Stomach	Adenocarcinoma	Prostate
13	M	51	Adenocarcinoma	Stomach	Squamous-cell carcinoma	Bile ducts
16	M	50	Adenocarcinoma	Stomach	Parenchymal-cell carcinoma	Liver
18	M	65	Adenocarcinoma	Stomach	Parenchymal-cell carcinoma	Liver

11	M	58	Adenocarcinoma	Rectum	Papillary adenocarcinoma	Prostate
15	M	63	Adenocarcinoma	Rectum	Papillary adenocarcinoma	Transverse colon
					Basal-cell epithelioma	Rectum
						Temple

The liver is involved in 5 cases, the prostate in 4, the pancreas in 3, the lung in 3, the uterus in 2, and the kidney in 2.

Two cases have 3 primary malignant lesions. Case 4 shows involvement of the prostate (adenocarcinoma), the middle third of the esophagus (squamous-cell epithelioma), and the stomach (spindle-cell sarcoma). Case 21 shows involvement of two distinct polypi in the fundus of the stomach (adenocarcinomas) and an infiltrating lesion in the pylorus (adenocarcinoma).

In 14 cases there are metastases from at least one of the lesions, and in 3 cases from both of the lesions. In 7 cases no metastases could be found.

Seventeen patients were males and 4 were females, a ratio of 4.2:1. Except in one instance (Warren and Gates), the published autopsy series show a comparable ratio of males to females. In the surgical series, however, the ratio

is slightly in favor of the females. The variation may be explained in part by the fact that while women are willing to submit to operation, it is more difficult to obtain permission for post-mortem examination of the female body.

TABLE VI

CASES IN WHICH ONE OF THE LESIONS ARISES FROM STRATIFIED SQUAMOUS EPITHELIUM

CASE NO.	SEX	AGE	LESION	ORGAN	LESION	ORGAN
2	M	44	Squamous-cell epithelioma	Scrotum	Bronchiogenic carcinoma	Lung

					Spindle-cell sarcoma	Stomach
6	M	56	Adenocarcinoma	Prostate	Adenocarcinoma	Transverse colon
10	M	66	Adenocarcinoma	Prostate	Bronchiogenic carcinoma	Lung
12	M	76	Adenocarcinoma	Prostate	Adenocarcinoma	Pancreas

The average age in this series is 58.4 years. The ages vary from 33 to 75 years, the ages being those at time of death. This average conforms with other published reports. It is slightly above the generally accepted age incidence for single malignant lesions, thereby lending credence to the clinical rule that those tumors which appear late in life are likely to be less rapidly lethal than those which appear early. Being less rapidly lethal, they do not cause the death of the host before a second lesion has time to develop.

COMMENT

The amassed data from several large series of autopsies from American institutions reveal that in 7,448 cases with malignant lesions there are 219 cases (2.8 per cent) with multiple malignant lesions. Kirshbaum and Shively, on the basis of their individual data, conclude "individuals may be endowed with a congenital, or acquired, predisposition toward tumor formation." Warren and Gates, and Austin, conclude that the incidence of multiple malignant lesions is

higher than can be explained on the basis of chance alone. A mathematical formula for computing the expected incidence of multiple malignant tumors when compared with the actual facts leads Bugher to conclude that the incidence is "equal to or greater than may be expected from chance alone." Although the percentage of multiples in the Bellevue series is somewhat below that of the total published series combined, the facts seem to warrant concurrence with those whose opinion it is that multiple malignant lesions occur more frequently than can be explained by chance alone. It seems fair to predict that as the life expectancy of patients with cancer is increased due to refinements in diagnosis and treatment, the incidence of multiple malignant tumors will increase and lend more convincing evidence in favor of the foregoing conclusion.

In reviewing the large number of autopsies necessary for the preparation of a paper of this nature, the frequency with which one encounters benign tumors in association with malignant tumors is striking. Studied in connection with family history, the problem is intriguing. It brings up the question of the interrelationship of hereditary predisposition for tumor formation and reaction to environment, and how that interrelationship may affect the health and happiness of the individual. The answer to the riddle is not yet apparent, but the possibility of theory becoming fact should interest the clinician now. With this information in mind he may help his patient and himself in two ways: first, in realizing that his diagnosis is not complete until he has ruled out the possibility of a second tumor once one is found; and, second, in realizing, as Stalker and co-workers have emphasized, the importance of free discussion and investigation of the other members of the family of a cancer patient for the possible presence or development of malignant disease.

SUMMARY

1. Twenty-one autopsies with multiple malignant lesions occurring in 1,044 autopsies with malignant lesions are reported. This is an incidence of 2.0 per cent.
2. There were 17 male patients and 4 females, with a combined average age incidence of 58.4 years.
3. Multiple malignant lesions are believed to occur more frequently than can be explained on a basis of chance alone.
4. The clinician is urged to rule out the possibility of a second tumor once one has been diagnosed.
5. The clinician is urged to discuss freely with the family of his patients with cancer the possible familial tendency of the disease.

CONGENITAL ABSENCE OF THE GALL BLADDER AND CYSTIC DUCT*

REPORT OF A CASE

WILLIAM C. GORDON, M.D., AND DAVID DRAGUTSKY, M.D.
NEW YORK, N. Y.

CONGENITAL anomalies of the gall bladder and the biliary ducts have been reported with increasing frequency in the past two decades, but they still remain relatively rare conditions. The importance of these structures in medicine and surgery warrants the description of these anomalies, which may at times assume major significance in diagnosis and treatment.

REPORT OF A CASE

S. L. (10922-1939), a 76-year-old white male, was admitted to the Metropolitan Hospital on Oct. 17, 1939, with complaints referable to the urinary system. He had received treatment for a mild diabetic condition, but had otherwise been in good health up to the present illness. The family history was irrelevant. There were no gastrointestinal symptoms, except for anorexia and constipation which had developed concomitantly with his urinary complaints.

After physical examination and laboratory work-up, the diagnosis was made of: (1) Fibrosis of prostate with contraction of the bladder neck. (2) Diabetes mellitus. (3) Arteriosclerotic heart disease—compensated. First-stage prostatectomy was performed on Nov. 8, 1939. The patient never rallied following the operation, but went steadily downhill despite all therapeutic measures. He developed an ascending urinary infection, and died Jan. 12, 1940.

During the course of the autopsy it was noted that the gall bladder and cystic duct could not be located. Acquainted with the rarity of this anomaly, we centered our attention on this focus. Careful examination of the skin of the anterior abdominal wall and of the underlying peritoneum did not reveal any scars. The site usually occupied by the gall bladder was free of adhesions or fibrous tissue, which may sometimes conceal an atrophic or shrunken gall

Received for publication, January 25, 1941.

bladder. The extrahepatic biliary ducts were carefully dissected and their continuity was traced into the duodenum. There were neither signs nor vestige of a cystic duct.

The liver weighed 1,430 Gm. and appeared normal as to shape and relations to the adjacent viscera. The normal markings of the gall bladder fossa were effaced. Glisson's capsule was thickened, and the surface of the liver was finely granular. The organ was firm and cut with resistance. The cut edges were sharp and distinct. The intrahepatic biliary ducts were moderately dilated and filled with viscid green bile mixed with granular debris. The right and left hepatic ducts issued from the transverse fissure, and immediately united to form a dilated common hepatic duct, which was 8 cm. long and had an average diameter of 1 cm. This duct was filled with viscid green bile and showed a small bulbous dilatation 0.5 cm. proximal to its entrance into the duodenum. The duodenal papilla appeared normal. Multiple sections of the liver failed to reveal any trace of an intrahepatic gall bladder. Careful examination of the common hepatic duct did not show any evidence of a cystic duct. The cystic artery was absent.

Microscopically, the capsule was irregularly thickened, and there was extensive subcapsular lymphocytic infiltration. The lobules were irregular in shape, but the relation of the central vein to the lobule was preserved. The perilobular connective tissue was increased and was infiltrated with lymphocytes, plasma cells, and occasional polymorphonuclear leucocytes. There was a proliferation of biliary canaliculi. The larger ducts were dilated and filled with plugs of bile. The hepatic parenchyma, for the most part, appeared normal. However, some cells, especially those at the periphery of the lobules, showed degenerative phenomena and some contained bile pigment. The blood vessels showed thickened walls and were engorged with blood. Sections of the capsule at the site usually occupied by the gall bladder failed to show any evidence of that structure.

The pancreas weighed 78 Gm. and was somewhat indurated. Microscopically, there was a slight increase in the interstitial connective tissue. The islets were abundant and appeared well preserved.

DISCUSSION

The significance of anatomic abnormalities of the gall bladder and biliary passages becomes increasingly important as our knowledge of this system progresses. It has been estimated that in at least 10 per cent of all autopsies, some anomaly of the gall bladder, bile ducts, or adjacent blood vessels can be demonstrated.

Agensis of the gall bladder and cystic duct has been described as an independent finding in about 40 cases. More commonly, this anomaly is found associated with other abnormalities of the hepatobiliary system. A total of about 60 cases have been described where absence of the gall bladder and cystic duct are accompanied by other structural defects of this system.

In 1928 Bower,¹ in an extensive review of the anomalies of this system, listed absence of the gall bladder and cystic duct as the fourth most rare anomaly of the hepatobiliary system. He cited 31 case reports of congenital absence of the gall bladder and cystic duct occurring independent of other

anomalies. In that same year, Alglave² added another case to this series. Since then cases have been reported, among others, by Danzis,⁵ Tallmadge,⁶ and Robertson and associates.⁷ Knox⁸ has reported two cases in a series of 2,000 autopsies. Mentzer⁹ and Nagel have seen the condition once each in a series of 1,600 autopsies. Emmert⁴ in 1931 reported the first case he had seen in twenty years of experience. Mackmull³ in 1930 reported the first case encountered by Schaeffer in 3,000 dissections. This case represents the first instance encountered at the Metropolitan Hospital in a series of 3,660 consecutive autopsies.

If the gall bladder is not found at autopsy or at operation, four possibilities must be borne in mind: (1) The gall bladder has been previously removed. (2) The gall bladder, due to repeated attacks of cholecystitis, has become atrophic or is buried in adhesions. (3) The gall bladder is intrahepatic or is otherwise abnormally located. (4) The gall bladder is congenitally absent.

In the case under discussion there was no history of any attacks of cholecystitis, nor of a cholecystectomy. There were no scars on the anterior abdominal wall nor on the peritoneal surface of the abdominal wall. There were no adhesions nor scar tissue at the gall bladder area. Multiple sections of the liver revealed no evidence of an intrahepatic gall bladder, nor could it be found in any other site. The only possibility that remained was that the gall bladder was congenitally absent.

The gall bladder and cystic duct are normally absent in certain species of animals (horse, mule, elephant). Some species may or may not have it (giraffe). In certain animals (pigeon) a gall bladder is present in embryonic life but disappears in later development.⁹ Its absence in man has been regarded by some writers as atavistic.

Congenital anomalies of the hepatobiliary system are of importance to the surgeon and clinician as well as to the pathologist and anatomist. These anomalies may lead to erroneous diagnoses, as when the gall bladder fails to visualize on cholecystography. They may also give rise to technical difficulties in surgical procedures. We recently had the opportunity to see a case where a cholecystogastrostomy was performed for common duct obstruction. The operation was technically successful, but at autopsy we found that the cystic duct ran an independent course up to immediately before the ampulla of Vater. There was not sufficient intraductile pressure to force the accumulated bile from the common duct up the long cystic duct into the gall bladder, and through the stoma between the gall bladder and the stomach. Had this anomaly been recognized at operation, an attempt might have been made to anastomose the widely dilated common hepatic duct to the stomach or duodenum, thereby prolonging the life of the patient.

Dilated bile ducts often, but not constantly, are found associated with absence of the gall bladder. Waring¹⁰ was the first to make the observation that "when the gall bladder and cystic duct are absent, the common duct is usually found to be enlarged a short distance above the entrance into the duodenum, so as to form a fusiform sac, which may serve to a certain extent, as a substitute for the gall bladder in the storage of bile which is secreted between the periods of digestion." Such a localized dilatation was found in this case in an already dilated common hepatic duct. It is interesting to note

that in agreement with Bower's statistics, the deceased showed dilated ducts and had lived to 76 years of age. Bower¹ states the average age of those who died with normal ducts was only 36, as compared with 52 years for those whose hepatic ducts were dilated. This is in accord with the fact that in some species of animals that are not provided with a gall bladder, the common duct dilates to compensate.

CONCLUSION

1. Congenital absence of the gall bladder and cystic duct is a relatively rare entity.

2. A case is reported where this condition was found at autopsy, but there were no symptoms clinically to indicate the presence of this anomaly.

3. Anomalies of the hepatobiliary system are of prime importance in the medical sciences.

OBSERVATIONS ON CAPILLARY PERMEABILITY AND INFLAMMATION IN THE SKIN OF SENSITIZED RABBITS*

R. H. RIGDON, B.S., M.D., AND ANNE HAYNES, B.S.
MEMPHIS, TENN.

TRYPAN blue when given intravenously to normal rabbits localizes and concentrates in areas of inflammation only during a specific interval. This interval is not determined by the presence of edema, hyperemia, or polymorphonuclear leucocytes.¹⁻³ It has been suggested that this colloidal dye localizes and concentrates in areas of inflammation as a "result of a temporary change which occurs in the epithelial cells, the connective tissue cells, and the endothelial cells of the capillaries. This change in the permeability of these cells results from the effect of xylol on the epithelial cells. The normal metabolism of the epithelial cells is disturbed, as shown by the presence of pyknosis, karyorrhexis, and necrosis. The results of the effects of this abnormal intercellular fluid on the capillary endothelium is, no doubt, a compensatory mechanism, permitting the passage of water and crystalloids at a more rapid rate than normal and also readily allowing the passage through the vessel wall of the cells, colloids, and plasma proteins."⁴

Ramsdell⁵ injected trypan blue intravenously to demonstrate the immediate skin reaction in rabbits and guinea pigs made hypersensitive to horse serum. The dye was injected intravenously immediately before 0.01 c.c. of horse serum was given intradermally. The infiltration of dye into these reactive sites, according to Ramsdell, "is at present to be looked upon as no more than a sort of indicator of the presence of an edematous change which is an expression of a toxic action upon the capillary endothelium." In discussing the observations of Ramsdell, Burrows⁶ states that "it would be of interest to know the results if these experiments were repeated with controls."

The present paper is first a report of our observations on the localization of trypan blue in the skin of normal and sensitized rabbits following the intradermal injection of horse serum, and secondly, our observations on the effect of trypan blue on the development of the local reaction following an intradermal injection of horse serum in the skin of sensitized rabbits.

METHODS AND MATERIALS

The skin of the rabbits is carefully shaven twenty-four hours or longer before the horse serum† is injected intradermally. The serum is injected at

†Supplied through the courtesy of Lederle Laboratories. The preservative is phenol ether.

varying intervals before 10 c.c. of a 0.2 per cent solution of trypan blue is given intravenously. The skin is observed for an hour for the appearance of a blue color.

A series of intravenous and intraperitoneal injections of horse serum is given for the production of sensitivity. The serum, obtained by bleeding from the heart, is titrated for precipitins in those rabbits used to study the effect of trypan blue on the skin reactions. The horse serum for intradermal injection is diluted with saline.

EXPERIMENTAL

Localization of Trypan Blue in Areas of Skin Injected With Horse Serum. Normal and Sensitized Rabbits.—Eight normal rabbits are injected intradermally with 0.2 c.c. of horse serum at the following intervals before 10 c.c. of a 0.2 per cent solution of trypan blue is given intravenously; twenty-four hours, five hours, three hours, one hour, thirty minutes, and immediately. In the normal rabbits only the last two areas, where the serum is injected immediately before the dye is given, become blue within a period of thirty minutes. In a group of six sensitized rabbits the dye localizes and concentrates in the areas of skin injected with the horse serum as long as three hours before the dye is given.

The greatest amount of dye concentrates in the areas injected with the serum the shortest time before the dye is given. A larger area of blue occurs at the site of the intradermal injection in the sensitized rabbits than in the normal rabbits.

There is only a small amount of edema in the skin at the site of the intradermal injections of the serum in the normal rabbits. In contrast to this, there is extensive edema and hyperemia in the skin where the horse serum is injected in the sensitized animals.

These observations show that a similar change occurs in the skin of both the normal and the sensitized rabbit following the intradermal injection of horse serum which permits the localization and concentration of trypan blue. This change persists longer, however, in the sensitized animals than in the normals. The localization and the concentration of this dye are not determined by either the presence or the absence of edema and hyperemia. There are considerable edema and hyperemia in the area where horse serum is injected twenty-four hours previous to the injection of the dye in the sensitized rabbit. The dye fails, however, to concentrate in the area. These observations seem to support the idea previously expressed that trypan blue localizes and concentrates in areas as a result of a change in the tissue cells. This change is a temporary one. The capillary endothelial cells, the tissue cells, and the epithelial cells are all apparently affected.

Effect of Trypan Blue on the Development of the Local Reaction in the Skin of Sensitized Rabbits.—It seems of interest in this experiment to study the effect of trypan blue on the development of the local reaction in sensitized animals. The results of the preceding experiments support the opinion previously expressed that trypan blue localizes and concentrates in areas of inflammation as a result of a temporary change in the endothelial cells, the con-

nective tissue cells, and the epithelial cells.⁴ Moon⁷ thinks that the above cells become sensitized and are injured directly by contact with the specific antigen. The presence of a colloid in these cells might influence their response to a specific antigen.

Five rabbits sensitized to horse serum are used in this experiment. Five days before the intradermal injection of the horse serum, the precipitin titer of the serum from these rabbits varied from 1:320 to 1:5,120. Ten cubic centimeters of a 0.2 per cent solution of trypan blue are injected intravenously into each of three of these rabbits, and into one control thirty hours and again six hours before the intradermal injection of 0.1 c.c. of the following dilutions of horse serum: undiluted, 1:10, 1:20, 1:40, 1:80, and 1:100. The skin is dark blue when the horse serum is injected. There are edema and hyperemia after twenty-four hours in each area of skin injected with the serum diluted as much as $\frac{1}{40}$ in each of the sensitized rabbits, while only a small reaction is present in the normal rabbits where undiluted horse serum is injected. The skin in the two sensitized rabbits without dye corresponds exactly with the reaction in the three rabbits given the trypan blue.

It may be concluded from this experiment that trypan blue does not affect the reaction of sensitized cells to a specific antigen.

DISCUSSION

The observations made in this experiment that trypan blue following an intravenous injection localizes and concentrates only during a specific interval following the intradermal injection of horse serum corresponds to other studies where this dye was found to localize and to concentrate in areas of inflammation produced by the local application of xylol only during a specific interval.^{1, 2} The present experiment also shows that the time in which trypan blue localizes and concentrates in an area is not determined by the presence of edema and hyperemia. The localization and the concentration of this colloidal dye in specific areas of skin supports the opinion that "the connective tissue and the vascular system differs as far as their functional state is concerned in sensitized and non-sensitized animals."⁸

There are many technical difficulties that one encounters in an attempt either to saturate or to block and then to study the reaction of specific cells. Cannon and his associates,⁹ and Jaffe¹⁰ have discussed these in considering the effect of blocking the reticulo-endothelial system on the formation of antibodies. The occurrence of edema and hyperemia at the site of the injection of the antigen in the sensitized rabbits given trypan blue similar to that occurring in rabbits without this dye certainly supports the opinion that "the storage of the dye does not affect the vital parts of the cells and in the dye-filled cells sufficient cytoplasm is left to carry on its metabolic processes. The cell also is able to take in more foreign material of the same or of another kind."¹⁰

These observations show that trypan blue localizes and concentrates in areas of skin injected with horse serum in sensitized rabbits during a specific interval. Furthermore, the greatest quantity of dye localizes and concentrates

in the area of skin injected for the shortest interval before the dye is given. These results suggest that immediately following the contact of the antigen with the sensitized cells a change occurs in the cells which permits the entrance of the colloidal dye. This change in the cell is transient. If the cell is completely destroyed, the coagulated cytoplasm may become blue by a diffusion of the colloidal dye from the intercellular fluid. In the rabbits where extensive injury occurs following the intradermal injection of horse serum, trypan blue may be observed to localize at the periphery of the lesion for as long as twenty-four hours. The localization of dye at the periphery of such a lesion must be differentiated from the localization of the dye which occurs throughout an area infiltrated by the horse serum. In the former, the cells are affected by being proximal to severely injured tissue, while in the latter the localization and the concentration of dye apparently results from the effects produced by the contact of the antigen with sensitized cells. It must be remembered that the metabolism of a cell may be disturbed by many different processes.

The Arthus' phenomenon is not influenced by the intravenous injection of ink given before and after sensitization.¹⁰ Although the reaction produced by the intradermal injection of horse serum into a sensitized rabbit may be different from the Arthus' phenomenon, it is of interest to know that trypan blue and ink do not affect the development of either the hypersensitive reaction or the Arthus' phenomenon.

SUMMARY

Trypan blue following an intravenous injection localizes and concentrates in areas of the rabbit's skin injected with horse serum if the serum is injected a short time before the dye is given. The time during which this dye localizes and concentrates in the skin is much longer in sensitized rabbits than it is in the skin of normal rabbits.

The localization and the concentration of trypan blue in areas of inflammation produced by horse serum are not determined by the presence of edema and hyperemia. This dye may not concentrate in all areas of edema and hyperemia, as shown by the failure of the dye to concentrate in areas of skin injected with horse serum twenty-four hours previously to the injection of the dye.

The presence of trypan blue in the tissues of a sensitized rabbit apparently does not affect the subsequent reaction that occurs when the antigen is injected intradermally.

PERCUSSION AND AUSCULTATORY PERCUSSION WITH A NEW INSTRUMENT*

LOUIS PELNER, M.D., BROOKLYN, N. Y.

IN ASCERTAINING the condition of the lungs, the size of the heart, great vessels, and viscera, no clinical method will ever have the finality of the roentgen ray. However, clinical means of evaluation of these facts, such as percussion and auscultation, are very important in the everyday practice of medicine, and any instrument that might improve our ability to recognize variations from normal justifies its existence. Moreover, competent evidence exists that percussion and its modifications can be fairly exact if done carefully.¹

Ever since Auenbrugger first published his results obtained from percussion in 1761, there have been attempts at variation of this clinical method.² The pleximeter was first invented by Piorry of Paris in 1828, and has been constantly improved since then. During the past three years, after working with several hollow pleximeters in order to magnify the sound conduction, I selected one which gave very satisfactory results. It consists of an instrument called the Fox localizing attachment, whose original purpose was for localizing cardiac murmurs in auscultation of the heart. For its new use it has been renamed the resonant pleximeter. The instrument consists of a localizing rod attached to a resonating chamber or sounding box, and is used in percussion instead of the pleximeter finger. The use of the resonant pleximeter in percussion of the chest, the heart borders and great vessels, gave a more discernible change between resonance, flatness, and dullness, than was possible without this aid.

While experimenting with this instrument, it was attempted to lead off the sound obtained from percussion directly to the ears of the examiner; in other words, to employ auscultatory percussion. It was found at first that the sound reaching the examiner's ears was too loud to be analyzed accurately. A plug of cotton inserted into the instrument where it is attached to the stethoscope tubing, sufficiently muffled the sound so that it can be properly evaluated. Loudness is not a criterion in its use. In the determination of the size of heart, it is preferable to start in the center of the anterior chest wall over the sternum and lightly percuss the pleximeter as it is slowly moved in each direction, until a change in quality of the sound is noted. Care must be taken to

*From the Department of Medicine, Jewish Hospital, Brooklyn, and the Department of Surgery, Beth Moses Hospital, Brooklyn.

Received for publication, December 31, 1940.

tap lightly with the ball of the finger, and to keep the strokes of the finger of approximately the same intensity. Care must also be taken that the localizing rod is between the ribs and not on the ribs, because the ribs conduct and emit sound differently than do the soft tissues. In our opinion other organs, such as the liver, spleen, consolidated areas in the chest and pleural effusions can also be percussed with fair accuracy. In the case of the liver, the instrument is placed over the apparent center of the liver anteriorly in the mid-clavicular line, and percussion is employed in each direction until a definite change in the quality of sound is elicited.

Fig. 1.—The resonant pleximeter for auscultatory percussion.

Certain difficulties inherent in the entire study of percussion must be considered at this point, so that any method may be properly evaluated.³ It must be understood that the word resonance can mean all things to all men. It cannot be accurately described. Each individual has his own standard for comparison. What is important is that the interpretation based on this standard should be the same in each case. To achieve this, nothing will take the place of practice. The percussion sound is produced by successive layers of the chest; a light stroke will bring into vibration the superficial layers and organs, and a heavy stroke the deeper layers. The pleximeter finger or instrument must be placed fairly snugly against the chest wall so as to damp the vibrations of the chest wall and bring out the vibrations of the tissue that we intend to percuss. Each percussion note consists of a predominant or fundamental tone and overtones. To evaluate the percussion note properly, we have to disregard the overtones. The percussion note also depends on such seemingly insignificant aspects, such as the pedestal on which the subjects rest, e.g., whether the subject stands on a stone floor or rests in bed. In the former case, there is a diminution of overtones; in the latter, an accentuation. It would, therefore, be better to have the subject standing or sitting on a hard object, rather than lying on a soft bed. This is a very important factor in reducing the number of overtones. The fundamental or predominant tone has several character-

istics, such as pitch and resonance. The pitch is determined by the rate of vibration of the organs percussed. If the rate of vibration is high, the pitch is high. The resonance of a body depends on its ability to keep vibrating when struck. If the body stops vibrating after it is struck, it is nonresonant. The pitch and resonance both depend on the tension, thickness, extent, and constitution of the matter of the body that is vibrating. The tension and thickness for example might be different in the same pathologic conditions in different individuals; thus a pneumothorax note may be of high or moderate pitch, depending on the tension in the pleural cavity.³ It can thus be seen that no instrument can possibly take the place of careful analysis of the percussion note.

HISTORICAL

The historical development of auscultatory percussion is interesting, because it shows how widely different the opinions of reliable observers can be as to its validity.⁴ The instrument here suggested, we believe, circumvents the difficulties experienced with the older instruments, because it utilizes a direct method of percussion, and an evaluation of this percussed area by auscultation. The following historical sketch will show the difficulties inherent in this system of clinical diagnosis, and will show how some of these have been surmounted.

Auscultatory percussion was first suggested by Laënnec in his *Traité de l'auscultation médiate*,⁵ but he did not use it to determine the size of the heart. Cammann and Clark⁶ were the first actually to attempt to determine the size of the heart. One end of a rod was placed against the chest wall of the subject and the other in the ear of the examiner. The examiner started percussing a distance away from the organ and gradually approached it. The end point was reached when there was a sudden increase in loudness as the organ was approached. Subsequently, nearly all improvements in auscultatory percussion have been variations of the observations of Cammann and Clark, the later investigators using percussion in concentric circles, either toward or away from a stethoscope placed over the organ. Bianchi⁷ in 1884 replaced the stethoscope with the phonendoscope, which had a rod with a small resonating chamber above it, and used scratching of the skin instead of percussion. In the ensuing years attention was centered in modifying the types of percussion used. Very light taps were used by some. Others used friction on the skin with the fingernails, going in concentric circles toward the organ.⁸ Still others used friction strokes with the brush, moving away from a stethoscope placed on an organ.⁹ Later, automatic hammers were used in conjunction with the stethoscope.

Most investigators placed great stock in their ability to outline the borders of the heart, abdominal masses, liver, and spleen with auscultatory percussion. Pal was able to diagnose two echinococcus cysts rather than one cyst in the liver of a patient.⁸ The enthusiasm of these early workers knew no bounds; some even felt able to discern the place of the interventricular septum. Then came the inevitable reaction with the researches of de la Camp¹⁰ and Schrwald.¹¹ These authors, working on cadavers, showed that by placing the stethoscope at a certain spot and percussing toward it, they were able to shift the area of

the apparent left border of the heart at will. They concluded that certain friction patterns that were assumed to map out the size of the heart were really the result of conduction of the percussed patterns along ribs, sternum, muscle, and bone, and thus could be shifted at will if the stethoscope was moved.

More modern investigators^{12, 13} seem to have overcome the objections of the early workers by using some object for direct percussion, and leading the sound thus elicited to the ears of the examiner. Auscultatory percussion with the resonant pleximeter falls into this class, although the instrument used was independently studied and does not resemble the other available instruments in any of its aspects.

COMMENT

The advantages of the instrument here discussed are:

1. It utilizes a direct percussion of the underlying structures and thus appears to do away with the disadvantage of the early methods.

2. The instrument can be easily procured at the present time and adapted for use.

SUMMARY

The instrument called the resonant pleximeter has been adapted for use in auscultatory percussion.

CLINICAL CHEMISTRY

THE INTRAVENOUS USE OF A SUCROSE-RINGER'S SOLUTION TO PRODUCE MAXIMAL DIURESIS*

HENRY F. HELMHOLZ, M.D., AND JESSE L. BOLLMAN, M.D.,
ROCHESTER, MINN.

IN A PREVIOUS communication we reported on the determination of the relative merits of a series of solutions to produce diuresis without danger to the animal or injury to its kidney. The most consistent producer of diuresis which approximated the intravenous intake was 8 per cent sucrose in half strength Ringer's solution. When this was given for periods of six hours to each of eight rabbits at a rate of 100 c.c. per kilogram per hour, the animals all survived, and the average output was 88 per cent of the amount given in the six-hour period. At the time we reported that two of the animals had received multiple six-hour injections without serious difficulty and with a slightly greater diuresis in the later injections. Recently, Anderson and Bethea called attention to the marked changes in the convoluted tubules of the kidneys of persons who shortly before death had received sucrose solutions intravenously. It is undoubtedly true that these changes did not benefit the individual, but it is also true that they probably did him very little harm. After our work on both rabbits and dogs it seems reasonable to assume that the cell of the convoluted tubule can appear very much injured histologically and yet function normally, and can in a short time again return to normal appearance.

Our object in this study was to determine the innocuousness of repeated six-hour intravenous injections of sucrose-Ringer's solution when given at intervals of about a week. For this purpose we used three rabbits of about 2.5 kg., each animal receiving 100 c.c. per kilogram per hour for six hours. One animal received six, the second ten, the third fourteen, injections.

The first animal was killed three days after the sixth injection; the second animal died during the fourth hour of the eleventh injection, death being caused by the accidental injection of air; and the third died a traumatic death six days after its left kidney had been removed. In view of the changes occurring in the urine twenty-four to forty-eight hours after the first injection, two other animals received injections, one a single, and the other two.

In order to determine its value in other species of animals, the same solution was used in dogs in quantities of 50 c.c. per kilogram per hour for six hours.

*From the Section on Pediatrics, the Mayo Clinic and the Division of Experimental Medicine, Mayo Foundation, Rochester, Minn.

Received for publication, December 12, 1940.

Three of the dogs received two injections only. The first dog received two injections on succeeding days; the second received the second injection forty-eight hours after the first; the third received the second injection one week after the first. The fourth dog, weighing 9.0 kg., received twenty-eight injections, twenty-seven before and one injection after removal of its left kidney. The following determinations were made routinely: blood urea, phenolsulfonphthalein output, output during six-hour diuresis, output during twenty-four-hour periods in the interval between injections, and specific gravity. Albumin, casts, erythrocytes, and leucocytes were tested for in the urine. A brief résumé of the experiments will show the trends without too much detail.

Fig. 1.—Output of urine after intravenous injection of sucrose-Ringer's solution as percentage of the amount injected.

Rabbit 1, weighing 2.3 kg., received six injections of 1,380 c.c. each of sucrose-Ringer's solution. The output varied from 1,150 to 1,440 c.c., or 83 to 104 per cent of the amount injected (Fig. 1); the average output was 90 per cent. The blood urea was 34 mg. per 100 c.c. before starting the injections, and at no time did it rise above 39 mg. The phenolsulfonphthalein output was 67 per cent before the start of injection and varied between 90 and 42 per cent. There was albumin, grade 3, in the urine in the second twelve-hour specimen after the first injection, and a trace on two occasions after that. Otherwise the urine was free of albumin. There were some erythrocytes and leucocytes in the specimen of urine taken forty-eight hours after the first injection; otherwise there were no formed elements. The animal was killed three days after the sixth injection. The findings at necropsy were essentially negative. Grossly, the kidneys were slightly enlarged and lighter in color than normal. Histologically, the convoluted tubules showed marked vacuolar degeneration and swelling of the cells, up to obliteration of the lumina of some of the tubules. The glomeruli looked compressed.

Rabbit 2, weighing 2.5 to 2.8 kg., was given ten injections of 1,620 c.c. each of sucrose-Ringer's solution. The output ranged from 1,235 to 1,810 c.c., or 76 to 112 per cent. Two of the last four injections produced diuresis of more than 100 per cent. The average output was 95.9 per cent of the amount injected. The blood urea ranged from 18 mg. per 100 c.c. to a high of 39 mg. after the fourth injection, with a return to 30 mg. at the time of death during the eleventh injection. The phenolsulfonphthalein output ranged from 60 to 97 per cent. There was albumin, grade 2, in the urine after the first injection only, with many casts after the first and seventh injections, and leucocytes after the first, second, seventh, and eighth injections. Fig. 1 (in the solid line) gives the percentage output of the various injections, showing the relatively better output in the later injections. The animal died and the kidneys were removed immediately and fixed in formalin. No cause of death other than air embolism was found, all the organs showing practically a normal state. The kidneys were not much enlarged.

Fig. 2.—Separation of tubules in the kidney of a rabbit. The kidney was removed during the fourth hour of the eleventh injection of sucrose-Ringer's solution ($\times 190$).

They were brownish red and slightly lighter than the normal kidneys. The capsule was not adherent. The pelvis looked normal. On section the cortex was a little lighter in color than the medulla.

Microscopically, the striking feature was the uniformity of the cortex. All cells of the convoluted tubules were light pink, owing to staining of a finely granular protoplasm small in amount. The collecting tubules were lined by a low epithelium, which stained a uniform red in contrast to the pink convoluted tubules. Most of the convoluted tubules had a good-sized lumen. A few were almost swelled shut. Most of the nuclei were oval; some were pyknotic and shrunken. Some glomeruli seemed to have been distended; in others the outer wall of the capsule was fairly close to the glomerular tufts. In many areas there

was a considerable separation of the tubules as if by fluid (edema). Fig. 2 illustrates this condition of the kidney parenchyma.

Rabbit 3, weighing 2.3 to 2.9 kg., received fourteen injections of 1,560 c.c. each of sucrose-Ringer's solution. The output during the six-hour periods ranged from 1,285 c.c. to 1,890 c.c., an output of from 82 to 121 per cent. The average output in the six-hour period was 101 per cent; in seven injections the output was greater than 100 per cent, and in seven it was less than 100 per cent. The blood urea ranged from 14 to 30 mg. per 100 c.c. The maximal reading was 30 mg. per 100 c.c. after the third injection; the reading before the fourteenth injection was 18 mg. per 100 c.c. The single reading of the phenolsulfonphthalein output taken before the first injection was 67 per cent. All readings after this ranged between 82 and 96 per cent, except that twenty-four hours after the eleventh injection, which was given two days after the tenth injection, the phenolsulfonphthalein output dropped to 44 per cent. Five days later it was again 91 per cent. There was albumin, grade 1, in the urine twenty-four hours after the first injection and albumin, grade 4, after the second, but no albumin in the urine after any of the other injections. There were casts, grade 2, erythrocytes, grade 1, and leucocytes, grade 2, after the second injection, but they were absent after the other injections. Three days after the fourteenth injection the left kidney was removed. Six days later the animal died as a result of an injury sustained at the time of biopsy. Fig. 1 shows the percentage output of rabbit 3.

Tissue was removed from the rabbit three days after the fourteenth injection and again nine days after this injection. The specimens removed three days after the fourteenth injection were two small wedge-shaped pieces taken from the left kidney. The epithelium of the convoluted tubules was about normal in height and had lost its light, granular appearance. The protoplasm again stained a definite red and was collected toward the basement membrane. Strands extended out into the lumen, possibly the remains of the vacuolar degeneration. In some areas the vacuolar degeneration still remained more marked than in others. The glomeruli showed no change, and no mitotic progress was found in the convoluted epithelial cells.

The specimen removed shortly after death on the ninth day after the fourteenth injection showed a normal picture in the right kidney, but considerable change in the left, from which two wedges of tissue had been removed. In the left the convoluted epithelium still showed some vacuolar degeneration, and most of the tubules were filled with a pink, finely granular detritus. The right kidney could be very simply described as the picture of the normal rabbit kidney. The three photomicrographs show well the rapid return to normal of the epithelium after a marked functional change which gives the kidney the peculiar appearance seen in Fig. 2. Fig. 3 shows a condition of the convoluted epithelium after a period of three days, and Fig. 4, an almost complete return to normal after nine days.

In order to check still further the effects of the first and second injections, which seem to give the most marked reaction in the urine, two other rabbits were given injections, one a single, and the other two.

Rabbit 4, weighing 3.3 kg., put out 94 per cent of the 1,980 c.c. of sucrose-Ringer's solution injected in the first six-hour period and 84 per cent in the second. After the first injection the twenty-four-hour urine showed albumin, grade 4+, no casts, and a considerable number of leucocytes. The following twenty-four-hour specimen had a trace of albumin and no leucocytes. The phenolsulfonphthalein output dropped from 93 to 40 per cent in the twenty-four-hour period after the first, and from 87 to 55 per cent in the twenty-four hours after the second injection. The left kidney was removed twenty-four hours after the second injection. There was marked hydropic degeneration. The restitution to normal in the right kidney removed a week later was not nearly as complete as in the experiment in which only one injection was given.

Fig. 3.—Appearance of the convoluted tubules in the kidney of a rabbit three days after the fourteenth injection of sucrose-Ringer's solution ($\times 145$).

Rabbit 5, weighing 2.2 kg., excreted 115 per cent of the 1,320 c.c. of sucrose-Ringer's solution intravenously injected in the six-hour period. In the twenty-four-hour period following the injection there were albumin, grade 4, erythrocytes, grade 1, and leucocytes, grade 1, but twenty-four hours later there was no albumin, erythrocytes, or leucocytes. The phenolsulfonphthalein output dropped from 75 to 49 per cent. The left kidney, removed twenty-four hours after the injection, showed marked hydropic degeneration and raggedness of cells. The right kidney was removed at necropsy one week later and showed practically a normal renal structure.

In order to determine what diuresis smaller quantities of 8 per cent sucrose in half strength Ringer's solution would produce, we gave two animals 50 c.c. of the solution per kilogram per hour for six hours, and two animals 25 c.c. per kilogram per hour.

Rabbit 6, weighing 2.1 kg., received 630 c.c. (50 c.c. per kilogram hour) and excreted 498 c.c. (38.5 c.c. per kilogram hour), or 79 per cent, in the six-hour

period. Rabbit 7, weighing 2.1 kg., received 630 c.c. (50 c.c. per kilogram hour) and excreted 446 c.c. (35.5 c.c. per kilogram hour), or 71 per cent, in the six-hour period. The average for the two rabbits was 75 per cent. Rabbit 6 was killed after twenty-four hours, and rabbit 7 after forty-eight hours. The changes were about as great as were those at a similar interval after injections of 100 c.c. per kilogram per hour for six hours. There was great vacuolar degeneration, irregularity of outline of the cells, and swelling of the cells to obliteration of the lumen of the tubules.

Fig. 4.—Return to normal of the convoluted tubules in the kidney of a rabbit nine days after the fourteenth injection of sucrose-Ringer's solution ($\times 125$).

The two animals that received only 25 c.c. per kilogram per hour for six hours excreted, one 31 per cent (8 c.c. per kilogram hour), and the other 50 per cent (12.5 c.c. per kilogram hour) of the amount injected, an average of 40 per cent, indicating the necessity of greater amounts of sucrose to produce diuresis. The histologic changes twenty-four and forty-eight hours after diuresis showed marked hydropic degeneration in the convoluted tubules. This was greater in the kidney removed after twenty-four hours than in the kidney removed after forty-eight hours.

Inasmuch as the rabbits that received 100 c.c. per kilogram per hour of the 8 per cent sucrose solution all survived, we thought it would be interesting to see the limit of the excretory capabilities of the rabbits' kidneys. Therefore, one animal was given 125 c.c. per kilogram per hour and another 150 c.c. per kilogram per hour. The animal receiving 125 c.c. per kilogram per hour put out 68 per cent (85 c.c. per kilogram hour) of the 2,172 c.c. injected, and showed no ill effect from the injection. The animal receiving 150 c.c. died forty-eight hours after the injection, having put out 88 per cent (132 c.c. per kilogram hour) of the 2,520 c.c. injected. Two other animals that received 150 c.c. per kilogram per hour for six hours died on the second day. One of the animals, which three

weeks before had received 125 c.c. per kilogram per hour, put out 92 per cent (138 c.c. per kilogram hour) of the 2,970 c.c. injected, and the other put out 88 per cent (132 c.c. per kilogram hour) of the 2,700 c.c. injected. It would seem that the limit that the rabbit can tolerate is between 125 and 150 c.c. per kilogram per hour. The average output for the three animals was 89 per cent of the amount injected (133.5 c.c. per kilogram hour), or 84 per cent of the body weight of the animal excreted in six hours, a very creditable performance.

In continuing our work with other animals, the dog seemed the one most easily available, and of such size that the total amounts injected would approximate amounts to be used for human injection.

Dog 1, weight 15.5 kg., received 50 c.c. per kilogram per hour for six hours on succeeding days. On the first day it received 4,620 c.c. in six hours and excreted 4,430 c.c. in the same time, an output of 96 per cent (47.6 c.c. per kilogram hour). The following day it received the same amount, but put out only 625 c.c., or 14 per cent (7 c.c. per kilogram hour), in the six-hour period. It gained 4 kg. this day, which it lost in the next three days. Its blood urea was 37 mg. per 100 c.c. before the first injection and 86 mg. before the second injection. The blood urea rose gradually to 233 mg. There were constantly many leucocytes in the urine and casts and erythrocytes after the first day. The phenolsulfonphthalein output fell to 10 per cent on the second day, but rose to 45 per cent the day before death. The animal died the fourth day after the first injection. At necropsy hemorrhages were found in the wall of the stomach and small and large bowel, as well as severe pyelitis with several huge abscesses in the kidneys. The epithelium showed marked vacuolar degeneration, but no necrosis of the epithelium.

Dog 2, weight 8.8 kg., received an intravenous injection of 2,640 c.c. in six hours and excreted 2,370 c.c. (45 c.c. per kilogram hour), or 90 per cent, during the first injection, and 1,875 c.c. (35.5 c.c. per kilogram hour), or 71 per cent, during the second injection the second day following. The animal appeared sick after the second injection and vomited two or three times daily. It died the fourth day after the first injection. Its phenolsulfonphthalein output was 80 per cent before the first injection, 65 per cent after the first, 65 per cent after the second injection, and 59 per cent two days after the second. There were albumin, grade 4, and erythrocytes, grade 4, after the first injection, as well as after the second injection. This animal also showed hemorrhages into the wall of the bowel and wall of the bladder. The kidney showed mild pyelitis, some sclerosis of the glomeruli, and marked changes in the convoluted tubules.

Dog 3, weight 12.6 kg., received two injections of 50 c.c. per kilogram per hour for six hours at an interval of one week. During the first injection it received 3,600 c.c. and excreted 3,000 (41.5 c.c. per kilogram hour), or 83 per cent, and at the second injection it received 3,780 c.c. and excreted 3,040 (40 c.c. per kilogram hour), or 80 per cent.

Dog 4, weight 9 kg., received twenty-eight injections of 50 c.c. per kilogram per hour for six hours. With one exception, when 2,675 c.c. was given, the animal received 2,790 c.c. during each six-hour period. The output varied from

1,830 c.c. during the first injection to 2,365 c.c. during the nineteenth injection, varying in output from 63 to 86 per cent of the amount injected, the average being 80 per cent (40 c.c. per kilogram hour) (Fig. 5). After the twenty-seventh injection the left kidney was removed. Five weeks later the output after injection of 2,790 c.c. was 2,100 c.c. (35.0 c.c. per kilogram per hour), or 75 per cent of the amount injected.

Fig. 5.—Output of urine after intravenous injection of sucrose-Ringer's solution as percentage of the amount injected.

The blood urea was 24 mg. per 100 c.c. before injection; it rose to 59 mg. after the first injection, went down to 33 mg. on the fourth day after the injection, rose again to 60 mg. after the second injection, and went down to 27 mg. on the second day. After this the range was between 18 and 38 mg. per 100 c.c., being 18 mg. and 20 mg. the day of the last two injections.

The phenolsulfonphthalein output was 80 per cent before the first injection; it fell to a trace at the end of twenty-four hours after injection, and was back to 63 per cent after forty-eight hours. It ranged between 58 and 94 per cent, with a reading of 26 per cent after the fifth injection and a trace twenty-four hours after the tenth and twelfth injections (given forty-eight hours after the ninth and eleventh injections).

There was albumin, grade 4, in the urine twenty-four hours after the first injection. The same was true after forty-eight hours. On the third day there was only a trace. Again after the tenth and eleventh injections there was albumin, grade 3, and after the twenty-fourth injection, albumin, grade 2.

Erythrocytes, grade 3, appeared after the first injection, and erythrocytes, grade 1, after the fourth, sixth, and seventh injections. Leucocytes in numbers were present after the first and eleventh injections, and a few after twenty-one injections. Constant catheterization probably accounted for these few cells. Nothing unusual occurred after the twenty-eighth injection, which was given to the dog after removal of the left kidney.

In these dogs as well as in the rabbits, the first injection seems to give rise to the most marked changes in the urinary findings and the phenolsulfonphthalein and urea values. It will be noted that the tenth, twelfth, and twenty-fourth injections were given forty-eight hours after the ninth, eleventh, and twenty-third injections, instead of the usual weekly interval, and this may account for the changes after these injections. On the other hand, it can be said that the twenty-fifth and twenty-seventh injections were given at two-day intervals without any change in the phenolsulfonphthalein output, rise in blood urea, or erythrocytes in the urine.

Fig. 6.—Condition of the kidney of Dog 4 five days after the twenty-seventh injection of sucrose-Ringer's solution ($\times 125$)

It is, of course, difficult to say why marked changes are observed after one injection and not after another of the same character. The changes observed were definitely temporary, and even repetition of the same insult produces neither the same acute change nor any permanent damage in the histologic structure or the function of the kidney.

The left kidney of the dog, removed five days after the twenty-seventh injection, showed no changes from the appearance of a normal dog's kidney (Fig. 6). This, together with the fact that the remaining kidney five weeks after left nephrectomy could excrete 75 per cent of the amount injected, shows excellent remaining functional capacity of the animal, whose two kidneys averaged 80 per cent in twenty-seven injections.

COMMENT

It would seem that in attempting to find a solution that, when given in large amounts intravenously, produces an equally large diuresis, the first requisite must be safety. Does the solution suggested have this requisite? From the number of injections given, we feel that we can safely say that the epithe-

lium, though markedly changed histologically, seems able to function in the changed condition. There is the second objection that more frequently the most severe reaction comes after the first injection with casts, albumin, and sometimes erythrocytes in the urine. This is, however, only a temporary reaction, and occurs only very occasionally after the later injections. Our object in this experiment is to determine the maximal excreting power of the kidney, so as to remain well within the limit of safety when applying these results to treatment in man.

It seems to us that after the results here obtained, it would be justifiable to use this solution clinically in cases in which there was an emergency in which it was necessary to produce rapid washing out of the urinary passages, as in acute pyelonephritis, to relieve obstruction with or without infection and high blood urea, to prevent ascending infection after operation on the prostate or other lower urinary obstruction, and also to produce good diuresis after a plastic operation on a hydronephrotic kidney.

SUMMARY

The rabbit can excrete from 90 to 100 per cent of fluid, representing from 54 to 60 per cent of its body weight, when given in the form of 8 per cent sucrose in half strength Ringer's solution at a rate of 100 c.c. per kilogram per hour for a six-hour period. Such injections may be repeated as often as every other day, with equally effective diuretic effect and no detectable impairment of renal function. A rabbit can excrete 89 per cent (133 c.c. per kilogram hour) of the injected fluid when given at a rate of 150 c.c. per kilogram per hour, a total of 84 per cent of its body weight in six hours, but most of these animals die within forty-eight hours after injection.

The dog can excrete 80 per cent of the fluid given intravenously in the form of 8 per cent sucrose in half strength Ringer's solution when given at a rate of 50 c.c. per kilogram per hour for a six-hour period weekly.

The kidneys in neither animal show any permanent damage after multiple injections, and regain their normal histologic structure in a period of ten days.

The first injection is the one after which the functional capacity of the kidney seems most likely to be lowered, but this lowering is only temporary.

VARIATIONS OF SERUM MAGNESIUM IN 52 NORMAL AND 440 PATHOLOGIC PATIENTS*

VICTOR G. HAURY, M.D., AND A. CANTAROW, M.D.
PHILADELPHIA, PA.

CONSIDERABLE data are being published relative to the variations of serum magnesium in health and disease. Upon examination of this information, it is apparent that too little is known at the present time to report with finality that certain abnormalities seen in man are due to a derangement of magnesium metabolism. A definite tendency toward a hypomagnesemia or hypermagnesemia seems to exist in certain clinical entities, and only after the accumulation of considerable data will it be possible to ascertain whether or not a disturbance in magnesium metabolism may play a role in the etiology of disease. Hence this investigation was undertaken.

EXPERIMENTAL

Serum magnesium determinations were made on 52 normal and 440 pathologic persons. The normal subjects were medical students and laboratory technicians. The pathologic cases were all hospitalized patients at the time that the blood samples were taken and analyzed. Since ingestion of food has no particular influence on the blood magnesium, no attempt was made to obtain the samples of blood at any particular time in reference to meals. The majority of the determinations were made by the modification of the titan yellow method,¹ yet a few were made by the method described by Briggs.²

As can be seen from Table I, the serum magnesium values in the majority of the normal persons (79 per cent) range between 2 and 3 mg. per 100 c.c. The average serum magnesium for the entire group is 2.48 mg. per 100 c.c. This corresponds very closely to the average mean of 2.35 mg. per 100 c.c. of serum, as reported by 17 different investigators (see Table II). In our group only one normal person was found to have a magnesium value slightly below 1.7 mg. We consider, therefore, 1.7 and 3.1 mg. of magnesium per 100 c.c. of serum as the lower and upper limits of normal, respectively.

Nothing unusual is noted in the values obtained from those patients suffering from endocrine disturbances. Our results on diabetic patients support the variability of blood magnesium as already noted by other investigators. In 12.5 per cent of the patients suffering from diabetes mellitus we found a low serum magnesium. This was previously reported by Blumgarten and Rohdenburg.¹⁹ In 15 (26 per cent) of our cases a hypermagnesemia occurred. This confirms the findings of Watchorn and McCance.⁵ ✓

*From the Department of Pharmacology, Jefferson Medical College, and the Laboratory of Biochemistry, Jefferson Hospital, Philadelphia.

This investigation was made possible through a grant from Parke, Davis & Co. to Jefferson Medical College for research in science.

Received for publication, January 3, 1941.

The few patients suffering from toxic thyroid gland and polyglandular disturbances, which we have examined, show that a low blood magnesium may prevail. Blumgarten and Rohdenberg¹⁹ report that 15 of their 45 patients suffering from goiter had a low blood magnesium. Recently, Soffer and co-workers²⁰ made the interesting observation that the ultrafiltrable magnesium in 31 patients with hyperthyroidism was low (average 64 per cent) when compared to that found in 14 normal persons (average 85.5 per cent).

More definite findings have been obtained in patients suffering from renal and circulatory diseases. The majority of the patients with chronic nephritis, as seen in Table I, reveal an elevated serum magnesium (average 3.56 mg. per 100 c.c.). Most of these patients also had an impairment of kidney function. It is interesting to note that those patients having hypertension associated with definite renal impairment also had an elevated serum magnesium (average 3.90 mg. per 100 c.c.). Hypertensive and arteriosclerotic patients, without apparent renal damage, had a definite though less marked elevation of blood magnesium. This would seem to bear out the inference of Beecher and Hamann²¹ that the concentration of this ion is increased in hypertension as a result of the associated kidney damage. Numerous reports have appeared in the literature which would indicate that a retention of magnesium is rather common in cases of renal insufficiency.^{5, 9, 10, 14, 21-25}

Those patients suffering from vasospastic diseases present a different type of picture. More than 17 per cent of the group have a hypomagnesemia. The group as a whole is somewhat below normal in so far as the mean blood magnesium is concerned (2.12 mg. per 100 c.c. of serum). From these figures it would appear that some relationship may exist between hypomagnesemia and spasticity of the smooth muscles in the blood vessels.

From Table I it may be noted that 23 per cent of the 26 patients suffering from malignant neoplasms have a low serum magnesium. Other investigators^{19, 26, 27} have reported similar findings. This ion has on occasion been implicated as one of the etiologic factors in the cause of cancer.²⁸

In the patients suffering from hepatic disorders, especially those associated with jaundice, a significant increase in the serum magnesium is noted. Beecher and Hamann,²¹ Blumgarten and Rohdenburg,¹⁹ and Jung²⁹ have reported similar findings. In this connection it is interesting to note that Rothman, Meranze, and Meranze³⁰ found the blood phosphatase to be high in cases of obstructive jaundice. Erdtmann³¹ had previously recorded that phosphatase activity is greatly increased by the addition of magnesium.

Far too few cases of infectious diseases have been studied to draw any conclusions from the results. In our patients 3 of the 5 cases of chronic arthritis studied had a low serum magnesium.

The blood of 8 women suffering from toxemia of pregnancy was studied. It seems significant that 3 of these should have a low serum magnesium. One of these patients who had a magnesium concentration below 1 mg. per 100 c.c. of serum also had severe convulsions. Probably the successful use of magnesium sulfate in the treatment of eclampsia³²⁻³⁵ depends, at least in some cases, upon the elevation of the blood magnesium to the proper physiologic level.

We studied 3 cases with orthopedic surgical conditions. In 2 of these a marked hypomagnesemia and in one a marked hypermagnesemia occurred. The 2 patients with hypomagnesemia were cases of ununited fractures of the patella and tibia, and their serum magnesium values were 0.96 and 0.80 mg. per 100 c.c. of serum, respectively. Further study revealed that the latter patient required an amputation of the limb one year after the above blood study was made. The patient with a hypermagnesemia of 4.4 mg. per 100 c.c. of serum suffered from intra-articular adhesions of the right shoulder with beginning ossification of the joint.

*For whole blood.

The 3 cases suggest to us the possibility that a deficiency of magnesium may be partly responsible for the delayed formation of callus. Conversely, a hypermagnesemia may play some etiologic role in the production of intra-articular adhesion and ossification.

In epilepsy a deficiency of magnesium was found in 2 of the 5 patients examined. This is in close agreement with the findings of Denis and Talbot,³⁶ Blumgarten and Rohdenburg,¹⁹ Wolf,³⁷ and Hirschfelder and Haury.³⁸ This is not surprising since the establishment of the close relationship between magnesium deficiency and convulsions.³⁹⁻⁴³ However, Greenberg and Aird⁴⁴ found the blood serum magnesium essentially normal in 22 patients with essential epilepsy.

SUMMARY

The results of serum magnesium determinations made in our laboratory on 52 normal and 440 pathologic patients are reported and the results are briefly discussed.

THE ABSORPTION OF STILBESTROL AND THEELIN FROM CYSTS OF SESAME AND PEANUT OILS*

FREDERICK E. EMERY, PH.D., CHARLES S. MATTHEWS, B.S., AND
EDWARD L. SCHWABE, M.S., BUFFALO, N. Y.

A LARGE number of animals treated in various ways with stilbestrol were autopsied during the last two years. Cysts were always found in the rats given oil by intramuscular injections and usually found after subcutaneous injections. The estrogenic content of the oil from many of these cysts was studied.

METHODS

The procedure followed was an outgrowth from experiments designed to test the minimal dose of stilbestrol. Failure to obtain consistent results with stilbestrol in oil led to a more careful study of the absorption of the oil. Data were taken from a total of 260 albino rats. Forty female rats used for minimal dose testing formed the beginning of these experiments. This group was given 0.3 c.c. of sesame oil in three doses of 0.1 c.c. each, 20 being injected intramuscularly and 20 in the subcutaneous tissue of the flank. A second group of 30 castrated mature female rats were injected subcutaneously in the back and 90 male rats intramuscularly in the hind legs with 1.0 mg. of stilbestrol in 1.0 c.c. of sesame oil. For the purpose of comparing theelin with stilbestrol, an additional 60 female rats were injected intramuscularly with 1.0 c.c. of either peanut oil or sesame oil containing 1.0 mg. of stilbestrol or theelin, and estrous cycles were followed for a period of thirty days (Fig. 4). Forty males injected intramuscularly with theelin were also added for cyst studies (Fig. 3). The needle was inserted to a depth of about 2 cm., and without further manipulation the 1.0 c.c. of the oil was deposited in one globule. The skin was pinched to

*From the Departments of Physiology and Materia Medica, University of Buffalo, Buffalo. Aided by a grant from Burroughs Wellcome and Company.
Received for publication, January 17, 1941.

prevent leakage of the oil. Some of these rats were autopsied each day for a period of forty days, and thereafter at various times up to a period of nine months after the injections were made. The oil from the cysts of each leg was collected separately, shaken in 5.0 c.c. of a salt solution (0.9 per cent), and the resulting oil emulsion given intraperitoneally to a castrated female rat. The estrous cycles were taken twice daily by the pipette method¹ as long as the rats remained in estrus.

RESULTS

The 40 rats that were given doses of 0.1 c.c. of sesame oil all showed multiple cyst formation in the muscles and the subcutaneous tissue of the flank. These cysts were usually small, 1 to 3 mm. in diameter, and full of clear oil.

Fig. 1.—A castrated female rat used for minimal dose testing of stilbestrol and given several subcutaneous injections of sesame oil in amounts of 0.1 c.c. each. The cysts of oil are typical of rats injected with sesame oil.

The cyst wall was firm and could easily be dissected free (Figs. 1 and 2). The quantity of stilbestrol injected was so small that tests for its estrogenic content from the encysted oil were not made. Only occasionally were large cysts present in these rats. Likewise the 30 rats injected with 1.0 c.c. of oil subcutaneously in the back usually showed similar cysts, but these were less abundant, indicating that only part of the oil as it gravitated downward from the back had remained in one area long enough to become encysted. At autopsy the 90 male rats which were injected intramuscularly with 1.0 c.c. of sesame oil showed larger cysts than the previously mentioned groups, and from these sufficient oil for testing could be obtained. The amount of oil collected from the cysts in the leg varied from 0.2 to 1.0 c.c. and diminished somewhat as postinjection time increased (Fig. 3). The cyst wall was found as early as the third day after the injections were made, and after five or six days it was always present. Up to at least a month after the cysts were formed, the oil was not always clear,

being frequently creamy to cheesy in consistency, and white in color. Although observations on cysts of longer duration are less in number, they indicate that the oil may be entirely clear, or clear with white, cheesy masses floating in it for at least nine months after treatment.

Fig. 2.—Cysts containing sesame oil dissected after being in the subcutaneous tissue and muscles of rats for varying periods up to nine months.

Fig. 3 depicts the activity of the stilbestrol remaining in the cystic oil after one to thirty-six days in the muscles. This curve, as first constructed from 60 tests, was very irregular. Since this might be expected from scattered data, an additional 30 tests were made at the irregular points. Therefore, it is fairly regular and shows that the percentage of rats giving positive vaginal smears diminish from 82 per cent on the first to third day to zero percentage at twenty-three days. One animal did not react when given 0.4 c.c. of cyst oil on the third day. This is difficult to evaluate, but since the slope of the curve is downward at four to six days and continues downward thereafter, these negative cases are not incidental to the technique of testing but rather indicate that stilbestrol was not present in sufficient amounts to give a positive vaginal reaction. Only one positive test was obtained after the twenty-first day, and this was from oil after twenty-nine days in the muscle (Fig. 3).

In a similar manner, 40 males were injected with peanut oil containing theelin to determine the theelin remaining in the cysts. Peanut oil, like sesame oil, became readily encysted. Theelin disappeared from these oil cysts sooner than the stilbestrol, the curve dropping sharply from the second to the eighth day. After the eleventh day further positive reactions were not found (Fig. 3). The difference between the amounts of stilbestrol and theelin remaining in the cystic oil may be explained by solubility. The theelin being more soluble in water was more readily removed by the tissue fluids surrounding the cysts, whereas the stilbestrol, although very soluble in oil, was insoluble in water.

The duration of estrus after a single injection of 1.0 c.c. of peanut oil containing 1.0 mg. of stilbestrol or theelin was determined in adult female rats. Fig. 4 shows the percentage of rats in estrus plotted against time in days. It is clearly seen that the curve for the stilbestrol-treated rats dropped slowly from the eighth to the twenty-first day, whereas the comparable curve for theelin absorption was considerably below this, having started downward

Fig. 3.—The per cent of castrated rats showing estrus after a single injection of oil from cysts containing stilbestrol (upper curve, 90 rats) and theelin (lower curve, 40 rats). Abscissa (lower), time in days that the oil was in the muscles of the donor rats. Abscissa (upper, below line), mean amounts of oil in cubic centimeters recovered each three-day period from the original 1.0 c.c. of sesame oil injected in the muscles of the donor rats. These figures also represent the amount of oil reinjected into the 90 test rats forming the upper curve. Abscissa (upper, above line), the 90 rats used for the stilbestrol curve subdivided to show the number of tests made at three-day intervals. The 90 male rats received 1 c.c. of sesame oil containing 1.0 mg. of stilbestrol. The 40 males received 1 c.c. of peanut oil containing 1.0 mg. of theelin. Both male groups were treated once only; the 1 c.c. of oil being injected in one globule in the muscles.

sharply on the fifth day and reached zero by the fourteenth day, thus indicating the more rapid absorption of theelin. These curves also conform in time, and to a large extent attest the validity of the estrous curves obtained with the oil from the cysts (compare Fig. 3 with Fig. 4). For the purpose of comparison the absorption of stilbestrol from both peanut oil and sesame oil is shown in Fig. 4. The two curves are identical until the ninth day and are only slightly separated thereafter, as indicated by the dotted line in Fig. 4.

DISCUSSION

The multiple cysts found in the subcutaneous tissue and muscles of rats given minimal doses of stilbestrol in a total of only 0.3 c.c. of sesame oil (Fig. 1) show that oil itself is poorly absorbed and leads to lack of confidence that stilbestrol could be uniformly absorbed through the fairly thick walls of the cysts. These oil pockets were found to be encysted by the fifth day, and the cyst wall appeared to become thicker and more durable for some time thereafter. Further evidence that sesame or peanut oil is an inadequate vehicle for stilbestrol was also obtained with larger doses of stilbestrol because they show that in some cases

Fig. 4.—Lower curve, A, the per cent of rats in estrus each day after 1.0 mg. of theelin in peanut oil was given intramuscularly. Upper curve, B, after 1.0 mg. of stilbestrol in 1.0 c.c. of peanut oil was injected intramuscularly. Dotted line, C, same in sesame oil. Twenty castrated rats were used in each of the three groups.

all the stilbestrol (1.0 mg.) may be absorbed in three days, while in other rats given identical treatment, the stilbestrol was still present after being in the muscles for twenty days (Fig. 3). Such a range of time for complete absorption probably would be less for smaller doses; but the uncertainty as to when all the stilbestrol would be absorbed makes minimal dose testing with oil solutions confusing.

After more than 150 tests were carefully studied, hope of determining the minimal dose of crystalline stilbestrol in oil was abandoned. Much confusion still exists in the literature concerning oil and aqueous solutions of estrogens. Korenchevsky, Dennison, and Schalit² found that oil remained several days after

intramuscular injections and discussed the uncertainty of oil absorption. Even more impressing data were obtained by Deanesly and Parkes,³ who found estrin in castor oil after fifteen days in the subcutaneous tissues of mice, and suggested that oil is a highly unsuitable medium for quantitative assay. On the other hand, Bülbring and Burn,⁴ using the weight of the uterus as an index of estrone activity, felt that their error in testing was small. The sensitivity of the uterus to small amounts of estrone in the blood^{5, 6} and the duration of the uterine growth test, which is usually beyond the time required for vaginal smear readings, give evidence that this test may be quite reliable for oil solutions. Also, estrogens in oil solutions deteriorate less readily than in aqueous solutions.⁷ These observations extended by these data led to the conclusion that oil was a vehicle from which absorption not only was slow and variable but also had the disadvantage of almost always becoming encapsulated and remaining in a cystic state for many months (up to nine months, Fig. 2; for as long as fifteen months not illustrated).

Oils differ in their ability to form cysts. Castor oil produced more cysts than sesame oil, and the latter produced more than olive oil.³ The present experiments indicate a similarity between sesame oil and peanut oil, judging by their ability to form cysts and by the duration of estrus induced by the stilbestrol remaining in these oil cysts (Fig. 4). Yet the wall of the sesame oil cysts appeared thicker than the wall of the cysts usually obtained with peanut oil.

SUMMARY

The formation of cysts following injections of sesame oil and peanut oil was observed in all rats (210) injected intramuscularly and was usually present in rats (50) injected subcutaneously. Oil obtained from the cysts was tested on castrated rats for stilbestrol and theelin. The curves for these tests showed that in some cases all the estrogenic activity was gone by the third day, but in a few rats some stilbestrol remained in the cysts even after twenty days. This is in marked contrast to theelin, in which case the time of retention was reduced to approximately nine days. These cysts, containing oil, remained in the tissues for many months.

Castrated rats were given 1.0 mg. of stilbestrol or theelin in 1.0 c.c. of peanut oil, and the estrous cycles were taken daily. These also confirmed the slow absorption of stilbestrol compared with theelin after a single oil injection.

HISTAMINASE

FURTHER LABORATORY STUDIES

MAURICE VAISBERG, M.D., BALDWIN, N. Y.

HISTAMINASE is the term applied to the histamine-inactivating property of aqueous extracts of certain animal body tissues. The properties and actions of histaminase closely resemble those of the enzymes, thus tentatively placing this "substance" in the category of enzymes or ferments. The property was first described by Eustis,¹ who reported inactivation of histamine with the pulp from the liver of a turkey buzzard. Most of the original research upon the characteristics of histaminase is described in the excellent papers of Best,² Best and McHenry,³ and McHenry and Gavin.⁴⁻⁷ Their exhaustive research has been the basic and guiding principle in this work and in previous work I have done. In the previous publication⁸ there was described the method of preparation, crude standardization, titration, and some clinical application of histaminase.

METHOD OF PREPARATION AND TITRATION

As previously described,⁸ hog kidney, after mincing, was defatted with acetone, dried with ether, and finely ground. The powder was extracted with phosphate buffer at pH 7.2 under toluene overnight in the incubator at 37° C. All the titrations and tests were performed with my method on my own left forearm, as previously described (except the experiments with trypsin). However, by further refinement, it was possible to arrive at an almost exact determination of the potency. The method follows: The sensitivity of the skin to histamine was first determined. One-tenth cubic centimeter of increasing dilutions of histamine phosphate was injected intracutaneously, and the size of the resulting wheals was measured and recorded.

CONCENTRATION	WHEELS IN MM.
1:10,000	18
1:100,000	17
1:1,000,000	15
1:10,000,000	12
1:100,000,000	9

Hence one could consistently determine one part in five million, or 0.05 gamma of histamine phosphate injected. Thus the skin is less sensitive than the hen's ileum,⁹ which can detect 0.01 gamma per cubic centimeter. In actual titration small Florence flasks were used. Into each flask measured amounts of histaminase solution in decreasing quantities were placed, e.g., 1 c.c. solution, 0.5 c.c. solution, 0.25 c.c. solution, etc. To each flask was then added 0.25 mg., or 0.25 c.c., of 1:1,000 histamine phosphate. The volume in each flask was made

up to 10 c.c. with phosphate buffer at pH 7.2. Since all the histamine was taken from one ampoule, only one intracutaneous test (from the mixture in any one flask) was necessary to determine the activity of the histamine. One-tenth cubic centimeter of the mixture from any one flask was injected intracutaneously, and the size of the wheal was measured and recorded. The concentration of the histamine was 1:40,000, and the size of the wheal was usually from 16 to 18 mm. The flasks were then incubated at 37° C. under toluene for twenty-four hours. Starting with the mixture containing the largest amount of histaminase solution, 0.1 c.c. was injected intracutaneously from each flask until one of the sites produced a wheal of over 10 mm. The potency was fixed at the point between the injection which failed to produce a wheal and the one which just produced a wheal. By definition, a unit of histaminase is the quantity of enzyme that inactivates 1 mg. of histamine during twenty-four hours' incubation at 37° C. in a phosphate buffer solution of pH 7. Hence the expression of unitage may vary, depending on whether histamine base, histamine hydrochloride, or histamine phosphate is used as a standard. One milligram of histamine base actually contains 1 mg. of histamine, whereas 1 mg. of histamine hydrochloride involves 0.6 mg. of histamine and 1 mg. of histamine phosphate produces only 0.3 mg. of histamine. Therefore, the actual histamine ratio, according to molecular weights, is 3:2:1, respectively. In this work, since histamine phosphate was used, it is necessary to divide the units expressed by 2 in order to obtain unitage against histamine hydrochloride and by 3 in order to obtain unitage as represented by histamine base. In the future it might be expedient to express all units in relation to histamine base.

According to McHenry and Gavin,⁴ extraction is best done by extracting one part of kidney powder with 18 parts of phosphate buffer. The solution is filtered and the powder is again extracted with a similar amount of phosphate buffer. In their procedure the filtrates were combined. This procedure was followed, but each of the filtrates was tested separately. The results obtained are indicated in Table I.

TABLE I
(Nitrogen is expressed as milligrams per cubic centimeter)

EXTRACTION	COLOR	POTENCY	PROTEIN NITROGEN	N.P.N.	TOTAL N
First	Amber	Over 10 units per cubic centimeter	0.90	0.29	1.19
Second	Light yellow	None	0.24	0.86	1.10

The following conclusions were drawn:

1. The potency is in a general way directly proportional to the depth of color of the original solution.
2. The second extraction had very little or no potency. It was, therefore, discarded as a step in the procedure.
3. The potency is related to the protein nitrogen fraction. The original extraction was finally modified so that each gram of powder was extracted with only 10 c.c. of phosphate buffer. By this method original solutions (filtrates), having from 5 to 75 units per cubic centimeter (average 12 units per cubic centimeter), were obtained.

PROPERTIES OF ORIGINAL SOLUTION (FIRST EXTRACTION)

I. The original solution can be clarified and sterilized by Seitz filtration without immediate loss in potency. It is clear, light to dark amber in color, has a strong odor of fresh animal tissue infusion, and is fairly stable at icebox temperature for about one to two months. However, solutions are rather unstable even at these temperatures, developing turbidities, flocculations, and precipitates, and generally losing a maximum of 50 per cent of their potency in from two to three months. One solution kept in the icebox for sixteen months developed a turbidity but maintained about 90 per cent of its original potency. Nevertheless, the solutions are sufficiently stable when fresh (about one month) for various in vitro experiments and for clinical use by intramuscular injection.

II. The solution is rather irritating and produces a distinct smart and pain on intramuscular injection, lasting ten minutes. An expedient maximum dose of 10 c.c. can be injected intramuscularly (average 120 units). Occasionally, one encounters the phenomenon described by Greenbaum¹⁰ of an intense local reaction coming on in a few hours, but this is no contraindication to continued treatment. In one case a severe asthmatic attack was induced in ten minutes, but further injections failed to produce attacks in the same case.

III. The solution can be concentrated to a dry tan powder, without loss of potency, by fanning in a cellophane bag. This dried powder is more permanently stable than the solution and is readily soluble in water. It is quite possible to prepare and store this powder aseptically in ampoules by means of the Adtevac,¹¹ Lyophile,¹² Cryochem¹³ process, or by some similar vacuum-refrigeration-concentration process. Due to lack of suitable equipment these latter procedures were not carried out.

IV. The effects of heat, hydrogen-ion concentration, and tryptic digestion confirm the report of McHenry and Gavin.⁴ If the histamine-histaminase mixture was adjusted to a pH of 5.0 or less previous to incubation, the histaminase was irreversibly inactivated. In the tryptic digestion experiments the trypsin used had an index or activity of 3.3 by Gross' method.¹⁴ A little of this trypsin was added to a solution of histaminase having a potency of 2 units per cubic centimeter and stored at icebox temperatures. An untreated control histaminase solution was similarly stored. After a few days the trypsin-treated histaminase and the control were incubated with histamine, and the titration was carried out on the virgin guinea pig uterus in the Dale bath. The usual skin titration was not carried out because injected trypsin has properties similar to those of snake venom.¹⁵ The following results were found:

1. Trypsin solution itself did not stimulate the guinea pig uterus.
2. Trypsin-treated histaminase did not stimulate the uterine strip.
3. The control mixture (after incubation) did not cause contraction.
4. The histamine trypsin-treated histaminase mixture (after incubation) caused a marked contraction of the uterine strip.

This showed that the histamine in result 4 was not destroyed and that the trypsin had inactivated the histaminase even at icebox temperatures. Any temperature of over 60° C. inactivated histaminase irreversibly.

V. Attempts to purify the solution by ultrafiltration were not successful. A potent amber histaminase solution, containing 7 units per cubic centimeter, was ultrafiltered with nitrogen pressure through two layers of No. 600 cellophane. While the pH of the solution was 7.2, the clear Nile green ultrafiltrate had a pH over 8.0.

The green ultrafiltrate did not possess any potency and was protein free. The material left on the cellophane was dark brown in color, did not redissolve easily, contained a lot of protein, and had a potency of only 3.5 units per cubic centimeter. Dialysis experiments showed failure of the active material to pass through the cellophane bag into the external buffer.

VI. Attempts to purify the enzyme by ammonium sulfate precipitation, followed by ice acetone extraction, in most instances produced a total loss of potency.

VII. The concentration of histaminase in beef and lamb kidneys is much less than in hog kidneys. Repeated attempts showed a maximum value of 1 unit per 20 c.c. in beef kidney solution, and 1 unit per 3 c.c. in lamb kidney solution. Both of these solutions were light yellow in color.

VIII. In evaluating the potency of hog kidney flesh autolysates (without defatting), freshly ground hog kidneys were allowed to autolyze under toluene in the incubator at 37° C. for from seven to fourteen days. It was found that the histaminase potency was always less than that obtained from the kidney powder. For example, one batch of kidney flesh produced solutions having a potency of 2 units per cubic centimeter. The solution obtained from powder from the same batch had a potency of from 5 to 25 units per cubic centimeter.

IX. As a demonstration of the enzymatic property of histaminase, a solution having a potency of about 1 unit per cubic centimeter was incubated with 1 mg. of histamine phosphate for twenty-four hours and showed the usual slight cloudiness. Skin test showed that histamine had been destroyed. The mixture was clarified by filtration, and another 1 mg. of histamine phosphate was added. After twenty-four hours' incubation, the histamine was found to be inactivated. A further milligram of histamine was added, and in twenty-four hours it was found to be destroyed. This type of reaction is rather characteristic of enzymes, as contrasted with purely chemical reactions.¹⁶

X. The effects of histaminase and histamine on the human skin and organism, as revealed in this study, may be of some interest. Eight batches of hog kidney powder and one batch each of lamb and beef kidney powder were prepared. Each batch usually contained about 200 Gm. of dried powder. From each batch about five lots of solution were prepared. This made a minimum of 50 lots of solution in a period of eight months. Each lot had an average number of 10 intracutaneous tests done. Hence, over 500 tests with histamine, histaminase, and mixtures of these were done on my left forearm. At no time was there any indication of any local refractoriness to histamine. Nor was there any evidence of increased sensitivity. The same site could be reinjected at any time from fifteen minutes to months after the first injections and still respond with a marked wheal. For example, a fresh site was injected with 0.1 c.c. of 1:10,000 histamine and a wheal of 18 mm. was developed. In about thirty minutes, when the flare was subsiding and the edges of the wheal were

less pronounced, 0.1 c.c. of 1:1,000 histamine phosphate was injected into the same puncture. In a few minutes a larger wheal with pseudopods developed. During the injections for over eight months it was natural that a large amount of histaminase would be injected and absorbed. This had no effect whatsoever on the subsequent histamine skin reactions. Two further experiments were performed:

(1) A potent histaminase solution containing 5 units per cubic centimeter, was injected intracutaneously in three sites, 0.3 c.c. being used at each site. Tests with 1:10,000 histamine phosphate in fifteen minutes, four hours, and twenty-four hours (one site at a time) produced prompt and typical histamine wheals.

(2) A highly potent histaminase solution, containing 15 units per cubic centimeter, was injected in two sites, 1 c.c. being injected intracutaneously at each site. Eighteen hours later one site was tested with 1:40,000 histamine phosphate and produced a wheal of 18 mm.; the other site was tested with 1:1,000 histamine phosphate and produced a wheal of 25 mm.

On several occasions after extensive skin testing, there was some lassitude, back pain, and axillary tenderness. Part of this may have been due to the protein injected. On two occasions there was a neuritis involving the left shoulder and arm. The first was relieved by cessations of the injections and short wave diathermy. The second neuritis responded very promptly to $\frac{3}{4}$ grain of oral propadrine. Despite the numerous hog protein injections, no sensitivity to pork developed.

DISCUSSION

The field of enzyme chemistry has made extraordinary advances in the past ten years. Organic or "living" enzymes are extremely labile substances sensitive to heat, cold, temperature gradients, hydrogen-ion concentration, electrolytic and colloidal concentrations, and many other physical and chemical factors. In order to secure sufficient final yields of high potency and purity, one must begin with hundreds of grams of original material.¹⁷ Enzyme chemists believe that they have recently isolated some of the enzymes in pure crystalline form after many years of intensive research.¹⁷ The most refined present preparations of histaminase are as yet far from the pure state attained for these other enzymes. The histaminase solutions used for injections are conglomerations of numerous aqueous extractives of hog kidney and intestinal mucosa. Separation of proteins in these solutions is quite incomplete, and various enzymes, hormones, salts, and inorganic materials in the mixture have not yet been completely investigated. Therefore, though the mixture inactivates histamine, we do not know as yet the reason for its reported beneficial effects.¹⁸ It must be realized that when the solution is given by injection, a large amount of nonspecific protein is given. In 10 c.c. there are about 9 mg. of protein nitrogen. Its beneficial effects by mouth (considering only the histaminase) are inexplicable in view of the *in vitro* experiments with tryptic digestion and the effect of pH below 5.0.

The enzymatic activity of solutions of histaminase seems definitely linked to the protein. Any attempt to remove all the protein results in inactivation

of the enzyme. This is further evidence that we are dealing with an enzyme in accordance with the present-day concept that organic enzymes are proteins or are closely allied to proteins.^{16, 17}

Although different persons have varying sensitivities to intracutaneous histamine, most of them have approximately the same sensitivity as described in this study. Hence, a method of titration of histaminase potency in human beings, using suitably titrated and standardized recompensed donors, is offered for clinical trial. The method is apparently sufficiently sensitive to meet all but the most exacting requirements. By using histamine from the same sterile lot in all titrations, the number of control injections can be reduced.

It was found that even though a batch of kidney powder was thoroughly mixed, different lots of solution from the batch extracted under exactly the same conditions would have different potencies. Therefore, it is inadvisable to test only one lot at a time in evaluating a batch of powder. Each lot of solution must be titrated separately.

The kidney histaminase variation in members of a species, determined by McHenry and Gavin,⁶ is compared with my findings in Table II.

TABLE II

(Figures represent milligrams of histamine base inactivated by 1 Gm. of kidney flesh)

ANIMAL	MC HENRY AND GAVIN	THIS WORK
Sheep	3.2	0.3 (lamb)
Ox	1.6	0.16 (steer)
Hog	3.6	10.0 average

It should be noted that only a small number of batches (one each) of lamb and beef kidney flesh and powder was prepared. Therefore, figures for lamb and steer may not be fully representative.

It has been found⁴ that there is a latent period *in vitro* before any inactivation of histamine occurs. This enzymatic property of latency is further demonstrated in the experiments in which skin sites heavily inoculated with potent histaminase solution failed to prevent the whealing reaction of histamine. This lack of "protection" may have some clinical significance.

A word of caution concerning the incubation during titration is in order. During the course of the investigation a peculiar property of histamine was observed. If 1 mg. of histamine phosphate (1 c.c. of 1:1,000) was added to 9 c.c. of phosphate buffer at pH 7.2 and tested intracutaneously, a wheal of 18 to 20 mm. was obtained. If the flask was then incubated at 37° C. for twenty-four hours *without* added toluene, the fluid would become somewhat cloudy. A skin test now would frequently show no histamine effect (lack of whealing), and the guinea pig uterus in the Dale bath would not respond. However, if a thin layer of toluene was added to the histamine in phosphate buffer previous to incubation, the solution would preserve its clarity and also its whealing effect indefinitely. The culture from the cloudy solution showed a gram-positive bacillus. Undoubtedly, the described destructive effect on histamine was due to the action of these air bacilli upon it.

Another paper will deal with the clinical results attained by the injection of potent histaminase solutions.¹⁹

SUMMARY

Further laboratory studies in the preparation, titration, properties, and purification of the enzyme-system histaminase are reported. A more accurate method of titration on human skin is described.

The physical properties of phosphate buffer solutions of histaminase and the effects of heat, pH, and trypsin are outlined. Several methods of purification and concentration are evaluated.

Further evidence that histaminase is an enzyme is adduced.

Some of the local and general effects of histamine and histaminase used over a long period of time are related.

The need for much more laboratory investigation in the purification and evaluation of the various components of the crude mixtures now available is stressed.

I wish to express my thanks to Mr. Cully, of Figge and Hutwelker, New York City, who so kindly supplied an unlimited number of fresh hog kidneys.

HISTAMINASE

RESULTS OF TREATMENT BY INTRAMUSCULAR INJECTION

MAURICE VAISBERG, M.D., BALDWIN, N. Y.

IN THE past five years interest has been stimulated in the histaminase treatment of allergic and allied conditions. A considerable literature has thus come into existence. Excellent partial reviews of previous clinical work are to be found in several articles.¹⁻⁵ Other papers⁶⁻¹⁰ have more complete surveys and extended bibliography. In this presentation, for the sake of brevity, very little reference will be made to other work.

The histaminase solutions used in this study were all prepared from fresh kidney tissue in the laboratory, as described in the paper on laboratory studies.¹² The solution used was the first phosphate buffer extraction of hog kidney powder, varied from light to dark amber in color, and was injected intramuscularly in all cases. Its potency ranged from 5 to 25 units per cubic centimeter (as against histamine phosphate). The usual maximum given at one time was generally 10 c.c. Early in each case injections were usually given twice a week and later, if the case improved, once a week.

The following types and numbers of cases were treated:

Asthma	7 (2 of these had neurodermatitis)
Neurodermatitis	4 (2 of these were of above asthma group)
Vasomotor rhinitis	3
Chronic urticaria	2
Serum sickness	} 1 each
Dermatographia	
Pruritus	
Migraine	
Heat allergy	
Total	19 cases

It is probably best to analyze these cases by tabulations, giving the case identification, duration of symptoms, average dose per week, number of weeks that histaminase was given, length of time of observation from inception of histaminase treatment and outcome. Each tabulation has appended a discussion of special features involved.

Case 5. The first series of injections was given simultaneously with nasal antrum washings. The patient improved rapidly, both as concerned asthma and neurodermatitis. But a relapse occurred despite continued treatment necessitating cessation of injections. During the period of nontherapy she rapidly got much worse. It was difficult to determine whether the histaminase

injections or the antrum washings were responsible for the initial improvement. The second series of injections starting thirteen weeks after the first series was given alone with temporary improvement only.

Case 6. Under treatment there were fewer attacks of dyspnea, but a moderate cough continued. Despite relief the ingestion of interdicted foods would produce slight wheezing.

TABLE I

ASTHMA

CASE	DURATION	DOSE PER WEEK IN UNITS	NO. OF WEEKS	TIME OF OBSERVATION IN MONTHS	OUTCOME
1. S. G. Simple asthma	16 yr.	40	10	2½	Helped at first, worse later
2. R. B. Simple asthma	5 yr.	30	2	10	Made much worse
3. J. B. Simple asthma	2 yr.	20	10	2½	Helped at first, worse later
4. L. K. With bronchiectasis	5 yr.	80	4	6	No better
5. E. K. Plus neurodermatitis	Life	70 0 90	10 13 2	5	Improved, then worse, etc. <i>See Discussion</i>
6. P. R. Plus infection	12 yr.	90	12	3	Better. <i>See Discussion</i>
7. A. B. Asthma Neurodermatitis	Life 6 mo.				<i>See under Case 2, Neurodermatitis group</i>

TABLE II

NEURODERMATITIS

CASE	DURATION	DOSE PER WEEK IN UNITS	NO. OF WEEKS	TIME OF OBSERVATION IN MONTHS	OUTCOME
1. E. K.	<i>See Case 5 under Asthma</i>				
2. A. B.	6 mo.	50 100	2 2	6	Improved at first, then worse. <i>See Discussion</i>
3. J. B.	1.5 yr.	556	1	2	Slight temporary aid. <i>See Discussion</i>
4. E. L.	Life	900	2	2	Temporary aid. <i>See Discussion</i>

Case 2. The asthma was controlled very well by routine allergic treatment, but the neurodermatitis persisted. The first injection of histaminase completely relieved the pruritus for a few days, but further injections caused recurrence of asthma and itching. A second series of injections twelve weeks after the first failed to produce any relief.

Case 3. Relief of pruritus was sporadic. The lesions cleared slightly. On release from the hospital there was a severe recurrence.

Case 4. The pruritus was variably relieved. The lesions cleared rapidly. The patient was treated in the hospital and relapsed badly four days after leaving hospital. There was, however, a marked psychic element in this case.

Case 2. The patient developed a tremendous wheal to a preliminary intracutaneous test precluding the use of hog histaminase. A preparation of lamb kidney histaminase having a potency of 1 unit per 3 c.c. was administered.

TABLE III
VASOMOTOR RHINITIS

CASE	DURATION	DOSE PER WEEK IN UNITS	NO. OF WEEKS	TIME OF OBSERVATION IN MONTHS	OUTCOME
1. H. S.	5 yr.	45	4	1 $\frac{1}{4}$	No help
2. G. D.	5 yr.	44	6	5	No help
3. J. D.	5 yr.	71	5	5	No help

TABLE IV
CHRONIC URTICARIA

CASE	DURATION	DOSE PER WEEK IN UNITS	NO. OF WEEKS	TIME OF OBSERVATION IN MONTHS	OUTCOME
1. N. G. Female	1 yr.	158	2	4	No help
2. N. G. Male	3 yr.	3 (lamb)	11	7	No help. <i>See Discussion</i>

Three units were given for eleven weeks without any help. Histamine injections produced a gratifying amelioration of all pruritus. However, the hives continued to appear, although they did not itch. This patient was sensitive to cold as demonstrated by the ice test.

TABLE V
MISCELLANEOUS

CASE	DURATION	TREATMENT	TIME OF OBSERVATION IN MONTHS	OUTCOME
E. S. Serum sickness	4 days	1 injection of 60 units	$\frac{1}{2}$	Permanent relief in 3 hours
E. J. Dermatographia	3 yr.	300 units in 2 weeks	2	No help
J. B. Pruritus	1 mo.	1 injection of 60 units	6	Permanent relief in few hours
G. T. Migraine	2 yr.	2 injections of 75 units each on successive days	2 days	No help
A. V. Heat allergy	5 yr.	<i>See Discussion</i>	12	Helped second time with large doses

The case of heat allergy (A. V.) was previously described in some preliminary work on histaminase.¹¹ At that time very small doses of histaminase (less than 1 unit) relieved the swelling of the feet occasioned by hot weather. The following summer nothing was done. The heat of the 1940 summer produced painful ankle edema again. It was now necessary to give about 160 units in two weeks to produce relief. The first injection induced an immediate violent asthmatic attack and a severe local reaction, but subsequent injections elicited only the local reaction in diminishing severity.

COMMENT

In all patients a preliminary intracutaneous test for pork sensitivity was performed with the solution. In one patient (2. N.G., chronic urticaria) the

local reaction was so large that lamb histaminase was substituted. In general, a mild or even moderate local reaction is no contraindication to treatment, although the usual care must be exercised. One case (A. V., heat allergy) developed an immediate constitutional reaction in ten minutes. One patient (A. B., asthma-neurodermatitis) had a delayed general effect of asthma in four hours after injection. Neither of these patients developed asthma on subsequent injections. Other general reactions, as reported by others, such as vertigo, nausea, flatulence, laxation, or headache;⁷ and fever, malaise, or joint pains⁸ were not observed in this series.

Local reactions, varying from mild redness and swelling to those described by Greenbaum,¹⁴ were seen in several cases. The latter consisted of erythematopapular areas at the site of injection, several inches across, with raised margins, marked itching, and local heat. After several inoculations the severity would diminish. There was never any evidence of necrosis. Local pain lasting ten minutes was elicited in all cases immediately upon injection of histaminase solution.

In evaluating any beneficial results one must take into account the well-known tendency of allergic diseases to improve and retrogress spontaneously. Hence, in a small series of cases as presented here, final conclusions cannot be drawn, and only the most meager clues or indications can be found as to the efficacy of this type of medication. For final statistical evaluation in this type of therapy, considering both the unknown quantities in the disease and in the medication, a very large series of cases with adequate controls (both auto- and hetero-) is indicated. In addition, any possible effect of nonspecific protein cannot be minimized. It should be remembered that each cubic centimeter of solution contains approximately 0.9 mg. of protein nitrogen.

Of the six cases treated for asthma, one was considerably improved, three were temporarily relieved, and two were not improved. One of the latter had a well-established bronchiectasis. Commenting, one could say that nonspecific protein might have given similar results.

Of the four cases of neurodermatitis, two (A. B. and E. K.) had variable relief, i.e., they were helped at one time and not at another; and two (J. B. and E. L.) who were hospitalized might have improved just from the hospital stay. Results attained here might have been obtained by other measures, such as calcium intravenously, bed rest, and even suggestion (hypnosis). However, the outstanding feature in all cases of pruritus, of whatever origin, where the medication did help, was the dramatic relief of itching in several hours.

None of the three cases of vasomotor rhinitis had the slightest relief.

Two cases of chronic urticaria had no relief whatsoever. This is in agreement with the much larger series of Piness and Miller,¹³ who employed an oral preparation.

One case of serum sickness responded dramatically. This is in accord with the work of Foshay and Hagebusch,¹ although they gave the preparation orally and their injections in much smaller doses.

There was no response in either the one case of dermatographia or in the single case of migraine.

The ankle edema due to heat required a much greater dose the second summer of treatment than the first.

It is somewhat difficult to correlate these results of intramuscular injections with those of other observers who have given the oral preparation, in view of the experiments in the laboratory presentation¹² which demonstrated that histaminase is inactivated by trypsin. Possibly this may explain the advocated necessity of larger doses orally.

As tentative conclusions in this study it might be stated that histaminase by injection, using our present preparations, may prove to be of value in resistant serum sickness, in idiopathic pruritus, and in heat and cold allergy. It may have a limited usefulness in neurodermatitis. It has an unpredictable effect on simple asthma, and no effect on vasomotor rhinitis, dermatographia, migraine, and chronic urticaria. It was not tried in hay fever.

Various lines of evidence, considered logically, lead to the impression that the beneficial effects of histaminase observed by various authors who have used the preparation both orally and by injection, are due to something else in the preparation other than the enzyme-system histaminase. The successful results reported by Altose,⁷ Goldberg,⁸ Foshay and Hagebusch,¹ Roth and Rynearson,¹⁵ Prickman and co-workers,¹⁶ and Roth and Horton,¹⁷ in its oral administration, despite the fact that histaminase is destroyed by stomach acidity, pepsin, and trypsin, indicate that there is something *other than* the enzyme which is responsible for the improvement. The work of Fox and Harned¹⁸ in which they used a cresolated solution of hog nasal mucosal extract by injection for chronic and acute rhinosinusitis with good results, point in the same direction. Cresol is known to destroy histaminase.¹⁹ The very properties of the enzyme-system histaminase militate against its ability to relieve the ill effects of the theoretical instantaneous release of histamine in anaphylactic shock and allergic reactions. The destruction of histamine by histaminase is not instantaneous and is generally quite slow. It is extremely doubtful that a sudden release of histamine in the body could be counteracted by administration of the enzyme before toxic effects had been produced. Thus, logically one is inclined to believe that any beneficial action reported in any condition for which histaminase was given orally or by injections was due to something else in the protein of the hog kidney or intestinal mucosa.

Finally, much more clinical work must be done with a potent, highly purified histaminase before the validity of any claims as to its efficacy as histaminase alone can be firmly established. Naturally, this involves further laboratory work in the purification and isolation of the enzyme and then the consistent evaluation of its effects in animals. Only when we have done these can we correctly interpret the separate effects of the histaminase and the other protein and nonprotein constituents of the solution.

REGIONAL AND SEASONAL VARIATIONS IN THE SERUM CHOLINE-ESTERASE OF HUMAN BEINGS AND DOGS*

ROBERT W. LACKEY, PH.D., AND DONALD SLAUGHTER, M.D., DALLAS, TEXAS

HALL and Lucas¹ in 1937 reported determinations of serum choline-esterase in 40 normal persons. They found values ranging from 1.32 to 3.61, with an average of 2.50. While determining serum esterase activity in a series of patients with peptic ulcer,² we had occasion to check normal values in this region. Determinations were made on 50 normal persons (students and secretaries). In this series were found values varying from 2.94 to 6.58, with an average of 4.72. The great difference between these values and those of Hall and Lucas assumes much importance in the comparison of pathologic cases with normals.

We are unable to offer any satisfactory explanation for the above discrepancy, except that possibility that a climatic or geographic factor is responsible. Without implying that choline-esterase is related to thyroid activity, the fact may be cited that Ring³ has shown that exposure to temperatures of 0° to 5° C. for periods of three weeks or more brings about a definite increase in thyroid activity in rats. Further, it is generally recognized that the normal standards established for basal metabolic rates in the colder climates are

*From the Laboratory of Physiology and Pharmacology, Baylor Medical School, Dallas. Received for publication, January 21, 1941.

approximately 15 per cent above those encountered in the southern states. However, if climatic conditions are responsible for the observed differences in choline-esterase values, it appears that they produce these changes very slowly in that no significant seasonal variations have been observed in our series nor have we been able to demonstrate seasonal variations in serum esterase activity in dogs.

To find whether sudden wide changes in body temperatures alter serum choline-esterase values, we have made determinations of choline-esterase activity in a series of six persons who were being subjected to artificial fever therapy. Blood samples were obtained from the patient immediately before entering the machine and again after five to seven hours during which time a body temperature of 104.6° to 106.6° F. had been attained.* The procedure revealed no consistent change in esterase values. The average value obtained in 9 determinations before the induction of fever was 4.21, whereas the average value afterward was 4.37.

In order to check this wide variation of serum choline-esterase values in human beings, we have made determinations of serum choline-esterase activity at weekly intervals for one year in a series of five dogs. We felt such a comparison would cross check these differences and also bring out any seasonal variations. Analyses were carried out according to the technique described by Hall and Lucas.¹ The values obtained are summarized in Table I in which, to avoid excessive length, is recorded only the mean value for the group of five animals for each date, together with the calculated standard deviation for that date.

*In one patient two treatments caused an elevation of body temperature to only 101° and 101.4° F.

Daily temperature records reveal that the plateau of the temperature curve extends from April 29 to September 16. The mean esterase value for this interval (twenty-one weeks) is 1.99, with a standard deviation* of 0.23. The mean value for the remainder of the twelve-month interval is 1.88, with a standard deviation of 0.33. Thus the values are slightly higher during the warmer period, but the difference is insignificant. It is worthy of note that, whereas the mean value for serum esterase activity (1.92) for this series of dogs is less than one-half that found in our series of normal human beings (4.72) in whom determinations were made concurrently, Hall and Lucas,¹ and Hall and Ettinger⁴ find no great difference in choline-esterase activity in the two species.

SUMMARY AND CONCLUSIONS

1. Normal human serum choline-esterase values in Texas appear to be approximately twice those reported from Toronto, but no consistent seasonal variations have been noted.

2. Elevation of body temperature by artificial fever therapy does not alter human serum choline-esterase values.

3. There is no significant seasonal variation in serum choline-esterase activity in normal dogs.

4. Whereas there appears to be a geographic or climatic difference in serum choline-esterase activity in the human being, values reported here for dogs approximate those reported from Toronto.

THE FRACTIONATION OF THE BLOOD IODINE*

I. FINDINGS IN PATIENTS WITH NORMAL THYROID FUNCTION AND WITH HYPOTHYROIDISM

ROBERT A. DAVISON, A.B., RICHARD W. ZOLLINGER, M.D., AND
GEORGE M. CURTIS, PH.D., M.D., COLUMBUS, OHIO

EXTENSIVE investigation has now firmly established the close relation between thyroid function and the quantity of iodine ordinarily circulating within the blood. In the absence of iodine administration in any form the blood iodine is usually decreased in patients with underactive thyroid glands and is increased in those with overactive thyroid glands. The normal range for the iodine content of whole blood varies considerably with the method used for its determination; nevertheless, all methods usually show an increased or decreased blood iodine in hyperthyroidism or hypothyroidism, respectively. These widely reported studies, and particularly the conclusions drawn from them, have formed the groundwork for further insight into the nature of disturbed thyroid function. Moreover, they have disclosed that significant knowledge may be derived from a careful differentiation of the various iodine compounds found in the blood and an interpretation of their possible metabolic significance.

At present, however, the status of both qualitative and quantitative microchemistry is such that the accurate identification and quantitation of these individual iodine-containing substances is hardly practicable. Nevertheless, there is a constant and ever-increasing attempt at the separation and identification of these compounds with an especial effort directed toward the *quantitative determination of the circulating thyroid hormone*.

Various methods have been employed in several attempts to quantitate the circulating thyroid hormone. Barkan¹ attempted to separate the "organic" blood iodine from the "inorganic" by precipitation with silver nitrate. Techniques based on the precipitation of thyroglobulin by a specific antithyroglobulin serum have been applied by other investigators.²⁻⁷ Alcohol has been employed by Perkin and Hurxthal⁸ and Trevorrow¹¹ as a precipitant in order to separate the blood iodine into soluble and insoluble fractions. Other workers⁹⁻¹¹ have employed acetone as the precipitating and thus the fractionating agent. McCleendon and his associates^{12-15, 17} employ methanol followed by acetone in their procedure for the fractionation of blood and tissue iodine.

In this report an attempt is made to evaluate the fractionation of the blood iodine in euthyroid persons of this region and in hypothyroid patients. We have employed an acetone procedure. Special attention is paid to the insoluble fraction. We presume that this fraction contains the circulating thyroid hormone.

All iodine values are in micrograms per cent.

METHOD

Fifty milliliters of oxalated blood is pipetted into three volumes of iodine-free absolute acetone. During the addition the mixture is agitated by rotating the flask in order to insure an even and fine precipitation of the blood proteins. The blood-acetone mixture is then allowed to stand at laboratory temperature for twelve hours to insure complete precipitation of the blood proteins and the maximum diffusion of acetone-soluble substances of the blood into the solvent.

The precipitate is then separated from the solution by filtration through a Buchner funnel, using a 11 cm. (589) "Blue Ribbon" Schleicher and Schull filter paper. The precipitate is then washed with 500 ml. of a 75 per cent acetone-water solution. It is further washed with 500 ml. of double-distilled iodine-free water. The filtrate and washings are pooled and analyzed for total iodine content. This is termed the acetone and water *soluble fraction*.

The remaining precipitate containing the acetone and water *insoluble fraction* is removed quantitatively from the funnel and analyzed for total iodine. The Matthews, Curtis, and Brode¹⁶ modification of the Leipert procedure was employed in all our determinations.

OBSERVATIONS

In 20 determinations made on 16 patients without detectable evidence of thyroid disease, the basal metabolic rate averaged plus 1, ranging from minus 16 to plus 20 (Table I). The whole blood iodine of this group varied from 3.5 to 7.1 micrograms per 100 c.c. averaging 4.45, which is normal for persons in this region on a nonconstant food regimen. The acetone and water *insoluble fraction* averaged 0.88, with variations of from 0.51 to 1.34 micrograms per 100 c.c. The acetone and water *insoluble fraction* does not closely parallel the basal metabolic rate. However, upon analysis of the individual patients with particular reference to the cause of the increased oxygen consumption, a clearer view of the significance of the *insoluble fraction* and its value as a differential diagnostic agent becomes apparent. In Tables I and III it may be noted that persons with increased basal metabolic rates not clinically referable to the thyroid gland present a normal or even lower than normal *insoluble fraction*.

The *insoluble fraction* even fluctuates in the same person (Table I). Moreover, this fluctuation shows only little relationship to the concurrent fluctuations in the basal metabolic rate. Although these individual fluctuations remain within the limits of what we have found to be the normal range for the insoluble blood iodine, they are difficult to comprehend without assuming an unexpectedly wide normal range in the circulating thyroid hormone. All determinations were made on bloods drawn in the morning in the postabsorptive state.

Table II presents a series of determinations made on patients with definite clinical evidence of hypothyroidism. The basal metabolic rate in this group averages minus 14, with variations from 0 to minus 28 per cent. The whole blood-iodine range is from 2.2 to 5.2, with an average of 3.6 micrograms per 100 c.c. The *insoluble fraction* averages 0.49, with variations from 0.23 in a patient with unusually well-developed hypothyroidism to 0.63 microgram per

100 c.c. in a patient with moderate but clinically obvious hypothyroidism. The upper limit of the insoluble blood iodine in this series is thus seen to overlap the lower limit of the insoluble blood iodine of the series of patients with normal thyroid function presented in Table I. (Fig. 1). However, this overlapping of

Fig. 1.—A comparison of the ranges of the insoluble blood iodine fraction in patients with normal thyroid function and with hypothyroidism.

Fig. 2.—A comparison of the ranges of the whole blood iodine in patients with normal thyroid function and with hypothyroidism.

the insoluble blood iodine is not as extensive as that of the total blood iodine of the same two series (Fig. 2). Due to theoretical variation in the sensitivity of individuals to the thyroid hormone, as well as from their variable physiologic requirements for the hormone, a certain amount of overlapping might even be

expected, especially in the borderline cases. *The insoluble blood iodine is consistently low in patients with hypothyroidism.*

Four euthyroid individuals with cardiovascular disease (Table III) showed a range in basal metabolic rate of from plus 9 to plus 46 per cent. Two had a normal blood iodine, and two had a total blood iodine below normal. In all except the one with uncomplicated essential hypertension, the insoluble blood iodine was below the lowest limit of normal. The patient with essential hypertension presented a normal insoluble blood iodine.

TABLE III

PATIENTS WITH DEFINITE CARDIOVASCULAR DISEASE AND WITHOUT CLINICAL EVIDENCE OF THYROID DISEASE

(Fractionated Blood Iodine)

NO.	AGE	SEX	B.M.R. PER CENT	ACETONE AND WATER SOLU- BLE I ₂	INSOLU- ABLE I ₂	TOTAL I ₂	DIAGNOSIS
1	65	F	Plus 29	2.88	0.42	3.30	Hypertension; congestive heart failure; (16 months after sub-total thyroidectomy for diffuse hyperplastic goiter with nodules)
2	72	M	Plus 9	2.70	0.42	3.12	General arteriosclerosis; arteriosclerotic heart disease
3	36	M	Plus 46	4.40	0.44	4.84	Hypertensive cardiovascular disease; early congestive failure
4	21	F	Plus 24	3.63	0.71	4.34	Essential hypertension without complications
Av.	48		Plus 27	3.40	0.50	3.90	

All iodine values are in micrograms per 100 c.c.

We interpret these findings (Table III), not as hypothyroidism masked by hypertension, but as a subdued thyroid secretion compensatory to the increased supply of oxygen to the tissues as a result of the hypertensive circulation. If the thyroid hormone acts as a catalyst, increasing the utilization of oxygen by the individual tissues, and the tissues are already receiving, through an increased circulation, an abundance of oxygen for their metabolic activity, then the thyroid gland may theoretically, at least, compensate by decreasing the supply of circulating thyroid hormone. Although this series is too small from which to conclude, the consistently low insoluble fraction is apparently of value in differentiating hypertension from hyperthyroidism.

SUMMARY AND CONCLUSIONS

A method for the fractionation of the blood iodine into an acetone and water *soluble* fraction and an acetone and water *insoluble* fraction is presented.

The acetone and water *insoluble blood iodine* averages 0.88, with variations of from 0.51 to 1.34 micrograms per 100 c.c. in euthyroid persons without cardiovascular disease.

The acetone and water *insoluble blood iodine* is consistently low in hypothyroidism and ranges from 0.23 to 0.63, with an average of 0.49 microgram per 100 c.c. The *insoluble blood iodine* in hypothyroidism does not show as extensive overlapping into the normal range as does the whole blood iodine.

Hypertensive individuals that are clinically euthyroid present a low normal to lower than normal *insoluble blood iodine*. The low *insoluble* fraction of hypertensive patients may prove to be of diagnostic value in differentiating uncomplicated hypertension from hyperthyroidism. The *insoluble blood iodine* fluctuates individually.

The acetone and water *insoluble blood iodine*, as determined by the method presented, would appear to contain the circulating thyroid hormone.

VALUES FOR ACETYLCHOLINE ESTERASE IN THE BLOOD SERUM OF NORMAL PERSONS AND PATIENTS WITH VARIOUS DISEASES*

HUGH R. BUTT, M.D., MANDRED W. COMFORT, M.D., THOMAS J. DRY, M.B., AND
ARNOLD E. OSTERBERG, PH.D., ROCHESTER, MINN.

THE presence of an enzyme of the blood capable of hydrolyzing acetylcholine was first suggested by Dale,¹ but not until eighteen years later was its specificity definitely demonstrated by the Stedmans and Easson.² Under the leadership of Stedman and his associates rapid progress was made in the study of the physiologic and chemical properties of acetylcholine esterase, but the possible clinical importance of this new enzyme received little attention. Several of the earlier clinical investigators observed wide variation of the esterase activity among various persons on whom studies were carried out over periods of many weeks^{3, 4} and for the most part were unable to correlate the acetylcholine esterase activity of the serum with any physiologic or pathologic condition.⁵

Within the past few years, however, several reports have appeared which suggest that the acetylcholine esterase activity of the blood serum may be altered in several clinical syndromes. Antopol and his associates,^{6, 7} and McArdle,⁸ reported low values for acetylcholine esterase in diseases of the liver and biliary tract, anemia, and hyperpyrexia. Milhorat⁵ considered the low values in his group of 109 patients to be the result of debility or severe cachexia, as did Jones and Stadie.⁹

The present study was undertaken to determine if possible the clinical significance of low or high values of acetylcholine esterase in the blood serum of man. The values for acetylcholine esterase were obtained at a constant temperature of 30° C. by utilizing the Cameron glass electrode assembly. Twenty cubic centimeters of the substrate of acetylcholine bromide, containing 2 mg. per cubic centimeter, were placed in a vessel which was surrounded by a continuously flowing current of water at 30° C. The substrate was brought to a pH value of 8.5 by the addition of approximately one drop of tenth-normal solution of sodium hydroxide. To this was added 0.2 c.c. of serum, and with manual stirring, enough hundredth normal solution of sodium hydroxide was added at intervals of five minutes for a period of thirty minutes to maintain the pH value of the substrate at 8.5. A microburette was used for this purpose. A control or blank determination was run from which serum was omitted; the value obtained was subtracted from the value obtained with the serum. Values are expressed as the total cubic centimeters of hundredth normal solution of sodium hydroxide necessary to maintain the substrate at pH 8.5 over a period of thirty minutes when 0.2 c.c. of serum is used.

*From the Division of Medicine and the Division of Biochemistry, the Mayo Clinic, Rochester.

Received for publication, November 19 1941.

VALUES IN BLOOD SERUM OF NORMAL PERSONS

Values for acetylcholine esterase in the blood serum of 47 normal men and 38 normal women were determined, a single determination for each individual being utilized for this purpose. Among the men the values ranged from 0.91 to 3.13, with an average of 2.06 ± 0.07 and a standard deviation of 0.48, and among the women from 0.90 to 2.99, with an average of 1.72 ± 0.08 and a standard deviation of 0.50. While the variability was essentially the same in the two sexes, the values in the serum of the women were definitely lower than among the men. The average value for the 85 men and women together was 1.90 and the standard deviation was 0.53. If we take a commonly utilized rule of statistics to accept plus or minus twice the standard deviation as the limits of significance (which will include 95 per cent of the cases), we can take 1.90 ± 1.06 or from about 0.85 to 3.0 as acceptable limits of normal variability.

TABLE I

VALUES FOR ACETYLCHOLINE ESTERASE IN A MISCELLANEOUS GROUP OF 24 PATIENTS

DIAGNOSIS	ACETYLCHOLINE ESTERASE (C.C.)*
Chronic nervous exhaustion	1.63
Erythromelalgia	2.45
Chronic duodenal ulcer with obstruction	0.76
Acute gouty arthritis and sinus bradycardia	1.95-1.65
Chronic duodenal ulcer	1.38
Epilepsy with periodic paralysis	
Between attacks	1.60
During an attack	1.65
Diabetes mellitus, grade 3	1.86
Obesity	2.31
Urticaria and angioneurotic edema	2.04-2.20
Postural hypotension	1.00
Sprue	1.64
Sprue	1.77-1.32
Average in first 12 cases	1.70
Chronic nervous exhaustion	1.05
Chronic nervous exhaustion	1.49
Anxiety neurosis	1.02
Psychoneurosis	1.67
Lipoma of neck	1.51
Indeterminate	1.13
Backache	1.72
Carcinoma of breast with pulmonary metastasis	1.70
Atopic eczema	1.26
Duodenal ulcer	1.73
Syphilis of the central nervous system; tabes dorsalis; causalgia	1.55
Sprue	0.92
Average in second 12 cases	1.40

*Cubic centimeters of 0.01 normal solution of sodium hydroxide.

Fluctuations in Values for Acetylcholine Esterase in Same Person.—The results given thus far are for one determination made for each of a number of individuals. The variation, therefore, represents the interindividual variability. In addition to this it was thought desirable to obtain some information concerning the variation of different determinations made for the same individual, that is, the intra-individual variation. Daily estimations were made on the serum of two normal persons. For one, six successive daily determinations had a mean of 0.86 ± 0.02 and a standard deviation of 0.06. For the other, seven

determinations had a mean of 1.17 ± 0.05 and a standard deviation of 0.14. The standard deviation measuring the intra-individual variability judged by these two persons together was 0.11. Thus it is seen that the intra-individual variability is about a fifth of the interindividual variability.

VALUES ASSOCIATED WITH VARIOUS DISEASES

Miscellaneous Group of Cases.—Values for acetylcholine esterase were determined in 24 patients in whom a variety of conditions was present. These included chronic nervous exhaustion, neurosis, epilepsy, obesity, urticaria, angioneurotic edema, duodenal ulcer, diabetes mellitus, syphilis of the central nervous system, sprue, postural hypotension, and arthritis (Table I). The values with one exception were within the range of normality (0.85 to 3.00), and the exception is not significant.

Hypertension.—Determinations of acetylcholine esterase were made in 13 patients with hypertension. The hypertension was of all grades of severity. The values ranged from 1.17 to 2.51 and averaged 1.58. Hypertension apparently does not produce changes in values for acetylcholine esterase.

Cardiac Disorders.—Values for acetylcholine esterase were determined in 12 patients with cardiac disorder. Our interest in this group was prompted by the possibility that the acetylcholine esterase content of the serum might be an index of the sympathetic-parasympathetic balance in cases of cardiac irritability, especially in cases of paroxysmal tachycardia of various types.

In a general way it can be stated that the values for this group fall within the limits of variation of the normal. This was found to be true in cases associated with organic cardiac lesions as well as in those in which periodic ectopic rhythms were the only cardiac abnormality. The values can be summarized as follows: 1.80 for a man 32 years old who had mitral stenosis and paroxysmal tachycardia (probably auricular fibrillation); 1.73 for a man 52 years old who had chronic auricular fibrillation associated with arteriosclerotic cardiac disease; 1.88 and 1.57, respectively, for two patients who recently had suffered from attacks of acute coronary thrombosis; 1.78 and 1.79, respectively, for two patients both aged 33 years who had minimal mitral endocarditis associated with considerable anxiety and heart consciousness. Six patients had paroxysmal tachycardia, but no demonstrable evidence of organic heart disease. The values of acetylcholine esterase in these patients were 2.14, 1.89, 1.36, 2.03, 2.31, and 3.31, respectively; all were determined while the cardiac rhythm was normal. Although the value in one was somewhat more than 3.00, which is the upper value of normality, only one such case was found among the 6 studied, and is not considered significant. In the first two cases the opportunity to determine levels of acetylcholine esterase during paroxysmal tachycardia also presented itself; readings were 2.00 and 1.39, respectively (as compared to the levels of 2.14 and 1.89, respectively, when the cardiac rhythm was normal). It is doubtful whether the variations noted are significantly great, but the change was at least in the same direction and the values were lower in the course of paroxysmal tachycardia than in the periods of normal rhythm. Before any definite conclusions could be drawn, however, the concentration of

acetylcholine esterase in serum would have to be determined at more frequent intervals before, during, and after paroxysmal tachycardia.

Pregnancy.—The values for acetylcholine esterase in the serum of 14 women, who either were pregnant at the time or had recently given birth to a child, were determined, and the results are listed in Table II. In two women readings were obtained before and after delivery. It will be noted that while the readings obtained in the course of pregnancy fall within the limits of variation of normal, with two exceptions they are all below the mean found for females (1.72). The mean in the 14 cases of pregnancy was (1.27 ± 0.08), and the difference from the mean for females is significant (0.45 ± 0.11). In one instance in which the occasion presented itself to repeat the determination of the value for acetylcholine esterase in the serum five months post partum, there was a considerable increase over the value obtained during the earlier months of pregnancy (3.02 as compared with 1.31). This finding in association with the rather low values noted during pregnancy prompts further investigation of the behavior of acetylcholine esterase in the serum in relation to pregnancy. Opportunity has not appeared thus far to determine values of acetylcholine esterase in the serum in cases of eclampsia.

TABLE II

VALUES FOR ACETYLCHOLINE ESTERASE DURING AND AFTER TERMINATION OF PREGNANCY

AGE OF PATIENT (YR.)	ANTE PARTUM		POST PARTUM	
	ACETYLCHOLINE ESTERASE (c.c.)*	MONTH OF PREGNANCY	ACETYLCHOLINE ESTERASE (c.c.)*	TIME AFTER DELIVERY
27	1.00	3		
26	1.37	3		
28	1.26	5		
34	1.24	3		
22	0.96	4		
21	1.11	5		
33	1.30	7		
21	1.24	7		
25	0.77	6		
32	1.74	8		
27			0.75	2 days
17†	1.06	5		
18†	2.01	8½		
29	1.31	3	3.02	5 mo.
26	1.39	1 day ante partum	1.51	1 day

*Cubic centimeter of 0.01 normal solution of sodium hydroxide.

†Two different pregnancies in same case.

Disease of Liver and Biliary Tract.—The values in 3 patients with catarrhal jaundice varied from 1.31 to 1.90. The values in 3 patients with stricture of the common bile duct and biliary cirrhosis were low; they were 1.03, 0.74, and 0.92. The values in 2 patients with neoplastic disease of the liver also were low, that is, 1.37 and 0.63. The values in 7 patients with marked hepatitis (surgical description) were low; they were 1.05, 0.69, 1.12, 1.54, 1.01, 0.62, and 0.97, and averaged 1.00. The two values of 0.62 and 0.69 were less than the lower limit of the range of normality. The values in 5 patients with compensated cirrhosis of the liver were just as low as in the group of cases of hepatitis; they were 0.82, 0.89, 0.99, 1.04, and 1.14, and averaged 0.98. It is to be noted

that the values were in the lowest range of values for normal persons, and in one case was slightly less than any of the normal values. The values in 7 patients with decompensated atrophic cirrhosis of the liver were very low; they were 0.22, 0.53, 0.50, 0.62, 0.46, 0.41, and 0.41, and averaged 0.43. In every case the values were much lower than the lowest values for normal persons and much lower than those encountered in severe hepatitis, biliary cirrhosis, and compensated cirrhosis. It is clear that the more extensive and severe the hepatic damage, the lower the values for acetylcholine esterase.

Pancreatic Disease.—The values for acetylcholine esterase were 1.46, 1.49, and 1.57 respectively, in 3 patients with subacute pancreatitis, and 1.23, 0.95, 0.18, 1.68, and 1.55 in 5 patients with chronic pancreatitis with recurring exacerbations. The values with the exception of one were within the range found in normal persons; in the patient in whom the value was 0.18, extensive pancreatic damage without recognizable hepatic disease was found at surgical exploration; as the condition of the patient improved, however, the value for acetylcholine esterase gradually increased to 1.03 fourteen days later. This one low value suggests that pancreatic disease may depress values for acetylcholine esterase, but no conclusions can be drawn.

The values for acetylcholine esterase in 8 patients with carcinoma of the head, and one of the body of the pancreas ranged from 0.77 to 1.47, and averaged 1.18. Only one value was below the normal range; in this patient there was extensive hepatic metastasis. In another patient the initial value was 1.43, but in ten days, as the condition became much worse, the value decreased to 0.61. When the degree of hepatic damage is considered in these cases, it is interesting that the values for acetylcholine esterase were as high as they were.

EFFECT OF VARIOUS DRUGS ON VALUES FOR ACETYLCHOLINE ESTERASE IN THE SERUM

While no systematic attempt was made to study the effect of various drugs on values for acetylcholine esterase, certain observations were recorded. Values were determined in a case of exophthalmic goiter and myasthenia gravis before the administration of 15 mg. of prostigmine orally and fifteen minutes after administration. The values decreased from 1.57 to 1.15. Values before and after two weeks of histaminase therapy in a patient with erythromelalgia were 2.45 and 2.55, respectively. Values before and ten minutes after intravenous administration of 50 mg. of thiamine chloride were 1.55 and 1.59, respectively. Values before and at the height of the pancreatic response to the administration of secretin intravenously were 1.73 and 1.69, respectively. Histaminase, thiamine chloride, and secretin had no effect in these cases on the values for acetylcholine esterase. On the other hand, prostigmine apparently decreased the values transiently.

VALUES IN PANCREATIC JUICE

The values for acetylcholine esterase in pancreatic juice obtained by duodenal tube were 0.14 and 0.0, respectively, ten and twenty minutes after stimulation with purified secretin, and that in pancreatic juice obtained from a human being, who had an external pancreatic fistula, was 0.03.

COMMENT

Our limited group of cases does not permit an elaborate statistical study, but from these data it seems safe to assume that in the presence of severe hepatic damage the acetylcholine esterase activity of the blood serum is decreased. We have observed that not all diseases of the liver or biliary tract are associated necessarily with a low value of acetylcholine esterase, but rather that the low value of acetylcholine esterase is usually a rough index of the amount of damage to the hepatic parenchyma. These findings are in close agreement with the results of McArdle.⁸ In 79 per cent of his 71 cases of disease of the liver, acetylcholine esterase values were below the range for normal adults. In 23 cases of cirrhosis of the liver the mean value was less than half of that of normal adults. There seems to be no satisfactory explanation for the decrease of acetylcholine esterase activity in disease of the liver. It has been suggested that bile salts *in vitro* will inhibit esterase activity,^{7, 10} but McArdle's work does not support this hypothesis.

A reduction in values during pregnancy also may be assumed, but a suitable explanation has not yet been advanced.

Our observations in man do not coincide with the observation of Ginsberg and his associates,¹¹ who found the pancreatic juice of a dog a rich source of acetylcholine esterase. Nor did the parenteral administration of 50 mg. of thiamine chloride to man have any effect on the esterase activity, although an inhibiting effect has been noted in the serum of horses and rats.¹²

SUMMARY

The values of acetylcholine esterase in the blood serum of normal persons and persons with various diseases were determined. For 47 normal men the mean value was 2.06 ± 0.07 and the standard deviation was 0.48. For 38 normal women the mean was 1.72 ± 0.08 and the standard deviation was 0.50. For all the normal persons taken together, the mean was 1.90 and the standard deviation was 0.53. Accepting ± 2 times the standard deviation as a reasonable range for normality, we set the range for normal persons as from 0.85 to 3.0.

Values for acetylcholine esterase in the blood serum were within the range of normal in patients with chronic nervous exhaustion, neurosis, diabetes mellitus, epilepsy, obesity, urticaria, angioneurotic edema, duodenal ulcer, syphilis of the central nervous system, sprue, postural hypotension, arthritis, hypertension of all degrees of severity, heart disease, both organic and that in which periodic ectopic rhythms were the only abnormality, and disease of the biliary tract without severe disease of the liver. Values for acetylcholine esterase were significantly low in pregnancy and in instances of severe hepatic damage. A loose parallelism existed between the values for acetylcholine esterase in the serum and the severity of liver disease. The lowest values were obtained in those patients in whom damage to the liver was most severe (decompensated portal cirrhosis).

Values for acetylcholine esterase in patients with pancreatic disease were, with one exception, within the range of normal. The single low value was so low that the possibility of disease of the pancreas lowering values must be entertained.

LABORATORY METHODS

GENERAL

A "TRANSPARENT CHOCOLATE AGAR" FOR THE PRIMARY ISOLATION OF THE NEISSERIA AND HEMOGLOBINOPHILES*

PHILIP STEINBERG, B.S., AND MOLLIE MOLLOV, M.S., JAMAICA, N. Y.

IT IS customary for the personnel of a bacteriologic laboratory to have available, in addition to blood agar, special media for the cultivation of such fastidious organisms as the gonococcus, meningococcus, and influenza bacillus. Many laboratories often employ different media for the isolation of each of the microorganisms mentioned. This imposes a considerable burden on the personnel and on the facilities of the laboratory.

Ever since Cohen and Fitzgerald¹ introduced a cooked blood agar (chocolate agar) and emphasized its usefulness for isolating *Hemophilus influenzae*, many investigators have employed such a medium for the cultivation of both the *Neisseria* and the hemoglobinophiles. McLeod and his co-workers,² Leahy and Carpenter,³ Reitzel and Kohl⁴ reported satisfactory results with various "chocolate agars" for the primary isolation of the gonococcus. Janeway,⁵ commenting on medical progress in bacteriology, recommends fresh "chocolate agar" plates or slants for the cultivation of the influenza bacillus and meningococcus from spinal fluid.

Recently, bacto proteose No. 3 agar (Difco⁶), enriched with either bacto hemoglobin, 5 per cent heated defibrinated or citrated blood, has been recommended for the cultivation of the *Neisseria*. The medium has been used successfully by Carpenter,⁷ and is highly recommended by Herrold,⁸ and Sulkin and Gottlieb.⁹

While the efficiency of the proteose No. 3 "chocolate agar" has been established, its opacity presents a disadvantage. Leahy and Carpenter,³ referring to the cultivation of the gonococcus, are of the opinion that the direct inspection of a "chocolate agar" plate is almost valueless when obscured by a luxuriant growth of other organisms. While the application of the oxidase reaction² decreases the difficulty due to the opacity of the medium, the promiscuous use of this test has been shown by Cohn and Kruger¹⁰ to have certain disadvantages. The isolation of small numbers of influenza bacilli, however, from a "chocolate agar" plate presents greater difficulty than is encountered in the isolation of the gonococcus and meningococcus, since no reaction similar to the oxidase test is available.

*From the Pathological Laboratory, Division of Bacteriology, Queens General Hospital, Jamaica.

Received for publication, May 26, 1941.

Proteose No. 3 "chocolate agar" possesses the qualities of an ideal medium, namely: stability of ingredients, a high degree of efficiency, and simplicity of composition and preparation. A medium of similar composition which would maintain all the above qualities and also be transparent seems very desirable.

It is conventional in the preparation of a "chocolate agar" to add 5 or 10 c.c. of sterile defibrinated or citrated blood to an agar base at 80° to 100° C., followed by pouring the so-called "chocolatized" ingredients into a Petri dish. It was found that by centrifuging the heated, coagulated blood, proteose No. 3 agar combination at a moderate speed, a supernatant fluid resulted which when poured into Petri dishes was transparent. The opaque sediment which is discarded never exceeds 2 c.c. for each 21 c.c. of the centrifuged mixture. The proteose No. 3 agar base was further enriched by the addition of a small amount of soluble starch (0.1 per cent) which aided in the production of larger colonies without overgrowth by other organisms.

Fig. 1.—Eighteen-hour, primary growth of *Hemophilus influenzae* on "transparent chocolate agar."

The medium in its final form was found to possess all the previously enumerated suitable qualities. Its simplicity of preparation and its ability to support luxuriant primary growth of the meningococcus, gonococcus, and influenza bacillus make it a very suitable medium for the routine of a clinical bacteriologic laboratory. In addition, its transparency presents an added advantage, for the colonies sought can be readily distinguished in mixed cultures.

Over a period of several months we have found this medium a satisfactory addition to the laboratory for the following multiple uses:

1. Routine cultures of spinal fluid and blood from cases of influenzal and epidemic meningitis.
2. Determination of the presence of meningococcus carriers, culturing the material from the nasopharynx.
3. Routine cultures of exudate from all types of gonococcal infections.

4. The isolation of the influenza bacillus from the nose, throat, and sputum.
 5. Isolation of *Hemophilus conjunctivitidis* from cases of conjunctivitis.
- We hope to analyze the results of this work in a future publication.

PREPARATION

Stock agar base. Suspend 1 Gm. of soluble starch in 1,000 c.c. of cold distilled water. Mix well. Add 45 Gm. of proteose No. 3 agar (Difco), and mix. Boil for one to two minutes to dissolve the agar and starch. Distribute to test tubes in 20 or 40 c.c. amounts, or as desired. Sterilize in autoclave for twenty minutes at 15 pounds pressure.

Fig. 2.

Fig. 3.

Fig. 2.—Eighteen-hour, aerobic, primary growth of the meningococcus.

Fig. 3.—Thirty-six-hour primary growth of the gonococcus in 10 per cent carbon dioxide atmosphere (oxidase positive).

Preparation of final medium. For every 20 c.c. of melted stock agar base, which has been cooled to about 50° C., add 1 c.c. of sterile defibrinated or citrated blood (human blood is used in our laboratory). Mix well. Heat mixture in water bath to 80° C. to 85° C. and allow to remain at the temperature until the blood begins to coagulate.

Centrifuge at 2,000 r.p.m. for one to two minutes.

Pour the supernatant fluid into a Petri dish or prepare slants.

DESCRIPTION OF COLONIES

In eighteen to twenty-four hours colonies of the influenza bacillus are colorless, transparent, and vary in diameter from 1 to 3 mm. On slants growth is luxuriant in eighteen hours, some strains producing colonies which are 2 to 3 mm. in diameter (Fig. 1).

In eighteen to twenty-four hours meningococci appear as circular, moist, shiny colonies, which are colorless by transmitted light. By reflected light the colonies are grayish and semiopaque. The size of the colonies is usually from 2 to 4 mm. in diameter (Fig. 2).

In twenty-four to thirty-six hours colonies of the gonococcus are semiopaque, colorless, opalescent, and have undulated margins. An overcrowded plate may reveal colonies which are 0.5 to 1 mm. in diameter. On a plate which allows ample growing space the colonies may reach 3 mm. in diameter (Fig. 3).

CONCLUSIONS

1. A modification of "chocolate agar," which is stable, simple to prepare, and yields a transparent medium, is presented.

2. Its ability to support initial growth of the influenza bacillus, meningococcus, and gonococcus make this medium a valuable addition to the clinical bacteriologic laboratory.

3. It eliminates the need for several separate media for the cultivation of the *Neisseria* and the hemoglobinophiles.

We wish to express our appreciation to Dr. Alfred Angrist, pathologist of Queens General Hospital, for his generous advice and cooperation.

TITRATION AND STANDARDIZATION OF ANTIGEN FOR THE EAGLE FLOCCULATION TEST*

A. HARRIS, STATEN ISLAND, N. Y.

ANTIGENS manufactured in this laboratory for the Eagle flocculation test have repeatedly failed to equal in reactivity standard antigen received from the test originator. Since a method for antigen adjustment has not been available, only two alternatives were open. Many antigen extracts could be made with the hope of finding one of suitable reactivity or a substandard antigen might be used in the test. Neither of these choices seemed to present an acceptable solution, and, for this reason, an investigation of the methods that might be used for the adjustment of this antigen was undertaken.

It is generally agreed that the reactivity of an antigen is influenced by changes in the sterol-lipoid ratio. Since the Eagle antigen closely approaches saturation with sterols, the possibility of increasing this component is limited. In a preliminary study, however, it has been found that an increase in the lipoid concentration approximating 100 per cent is possible without necessitating a reduction in the specified sterol concentration. It was also shown that, although some antigen preparations could be adjusted to a satisfactory level through an increase in lipoid concentration, others could not be rendered satisfactory by this procedure alone.

Eagle¹ recognized that the electrolyte concentration of the saline diluent may also influence the reactivity level of the antigen, but implied that too great a concentration may have deleterious effects. The results obtained by the combined use of these methods are presented.

Four antigens were prepared from commercial beef heart powder in exact accordance with the published technique of the originator.² Sterolization was carried out with Pfanstiehl cholesterol and Difco corn germ sterol. Dilutions of each of these antigens in 0.85 per cent saline (1 part antigen with 2 parts saline) were prepared and stored in the refrigerator for twenty-four hours. For control purposes a similar antigen dilution was prepared from standard antigen that had been obtained from the originator. These stock antigen dilutions were then rediluted with eight parts of 4 per cent saline and tested with serial serum dilutions.

Serum dilutions for the titration of antigens were prepared by diluting previously tested, pooled, positive sera in negative serum, care being exercised to insure adequate mixing. The following dilution schedule was used:

Tube 1.	Positive serum -	3 c.c.	
Tube 2.	Positive serum -	2 c.c.	Plus negative serum - 2 c.c.

*From the Venereal Disease Research Laboratory, United States Marine Hospital, Staten Island.

Received for publication, May 26, 1941.

Tube 3.	Positive serum -	1 c.c.	Plus negative serum -	3 c.c.
Tube 4.	Positive serum -	0.5 c.c.	Plus negative serum -	3.5 c.c.
Tube 5.	Serum from tube 2 -	0.5 c.c.	Plus negative serum -	3.5 c.c.
Tube 6.	Serum from tube 3 -	0.5 c.c.	Plus negative serum -	3.5 c.c.
Tube 7.	Serum from tube 4 -	0.5 c.c.	Plus negative serum -	3.5 c.c.
Tube 8.	Serum from tube 5 -	0.5 c.c.	Plus negative serum -	3.5 c.c.
Tube 9.	Negative serum -	3 c.c.		
Tube 10.	Negative serum -	3 c.c.		

The results of the preliminary titration of these four antigens and the control are shown in Table I. As indicated in this table the control or standard antigen gave some degree of positivity in the seventh dilution, whereas the trial preparations gave negative macroscopic and microscopic readings considerably above this level. On this basis the trial antigens were not considered as having standard reactivity.

In an effort to adjust these four antigens to the level of reactivity of the control, the method of increasing lipid content was utilized. This was accomplished by evaporating alcohol from measured portions of the unsterolized antigens until reductions to three-fourth and one-half the original volumes were obtained. Thus, when 100 ml. of antigen were reduced to 75 ml., a 33 per cent increase in lipid content was obtained, and when further reduction to 50 ml. was accomplished, a 100 per cent increase in lipid content was effected. These concentrated antigens were sterolized and filtered, and stock antigen dilutions were prepared as previously described. After twenty-four hours' refrigeration portions of each of these stock antigen dilutions were rediluted with eight volumes of 4 per cent, 6 per cent, 8 per cent, and 10 per cent salines, and retitrated against standard antigen using the previously described serum dilutions. To eliminate duplication of data only one protocol, considered to be representative of the group, is presented in Table II.

The findings indicate that antigen A was not adjusted to standard reactivity by the use of increased saline concentrations alone. Nor did increased lipid contents of 33 per cent, or 100 per cent, attain a satisfactory reactivity level when used with 4 per cent saline. However, a reactivity as sensitive as that of the standard antigen was obtained at two points: 33 per cent increased lipid with 10 per cent saline and 100 per cent increased lipid with 8 per cent

saline. Antigen with 33 per cent increased lipid when used with 10 per cent saline, although sufficiently reactive with positive sera, gave unsatisfactory results (see Discussion) in the negative serum tests, so the final adjustment chosen for this antigen was 100 per cent increase of lipoids with 8 per cent saline as the secondary diluent. Similar titrations of the other three antigens, designated 100 per cent increase in lipoids with 8 per cent saline, in one instance, and 100 per cent increase in lipoids with 6 per cent saline, in the other two, as the proper adjustment end points. All four of these antigens, after being adjusted in accordance with the titration results, were found to be of standard reactivity as compared against standard antigen when tested with positive and negative sera.

Either 0.4 c.c. of serum plus 0.2 c.c. of antigen dilution, or 0.2 c.c. of serum with 0.1 c.c. of antigen dilution may be used.

P, D, N—Positive, doubtful, and negative *macroscopic* readings.

p, d, n—Positive, doubtful, and negative *microscopic* readings.

*Swirl appearance missing.

DISCUSSION

The titration results presented in Table II show that the unadjusted antigen and the antigen containing 33 per cent increased lipoids gave rough microscopic pictures with negative sera when the 10 per cent saline diluent was employed. In these tubes the typical negative swirl was missing, the gross appearance being more chalky than usual. For this reason, these adjustment end points could not be considered suitable, even though a satisfactory reactivity with positive serum was attained.

These microscopic readings are considered an essential part of the titration, since they allow acute differential observations to be made. This is especially necessary in the negative serum tests so that an antigen adjustment can be made that will not give rough negative microscopic pictures. However, if two or more

adjustments are found to be equally good, the lesser lipid content with the lower saline concentration is probably to be preferred.

The level of reactivity that is now considered satisfactory for any test antigen is chosen by the author of that particular test. If, for some reason, the test author decides to raise or lower the test sensitivity level by changing the antigen reactivity, readjustments of antigen and saline can be made that will reproduce the desired result. For this reason, it is necessary that a standard antigen be available for comparative antigen titrations.

However, since the two antigen adjustments used are quantitative in nature, it is not presumed that sufficient correction can be obtained by these methods alone to compensate for any qualitative changes that may occur in some beef heart powder. Such unsatisfactory beef heart powder has not been encountered in this laboratory to date.

SUMMARY

Four Eagle flocculation antigens prepared from commercial beef heart powders were found to have varied reactivity, none of which were equal in reactivity to standard antigen obtained from Eagle.

A titration method for the comparison of antigen reactivity and a procedure which will allow the accurate adjustment of Eagle flocculation antigen is described.

A STUDY OF RECENTLY ISOLATED STRAINS OF STAPHYLOCOCCI AND THEIR ABILITY TO COAGULATE HUMAN PLASMA*

R. B. DIENST, PH.D., AUGUSTA, GA.

MOST of the literature published the last few years on the various laboratory methods used to determine pathogenicity of staphylococci has not stressed the value of the plasma-coagulase reaction. Chapman¹ and his co-workers discussed the value of this test as compared to the hemolysis of blood, the pathogenicity for rabbits, and the agglutination test. These investigators, however, did not correlate the ability to coagulate plasma with the source of the strain. Their observations were made on five thousand strains of staphylococci with no classification as to their source. Fisher,² reporting on thirty strains isolated from human staphylococci lesions, found that all exhibited the ability to coagulate plasma.

The present study was made on 65 freshly isolated strains of staphylococci. Nineteen of these strains were isolated from patients with clinical manifestations

*From the University of Georgia School of Medicine, Augusta.

†Cultures obtained from the Department of Bacteriology and Parasitology at the University of Chicago through the courtesy of Dr. G. M. Dack.

Received for publication, May 27, 1941.

of staphylococcus infection. Thirteen were collected from samples of raw milk, 24 were isolated from the air as contaminants, and nine were strains recovered from outbreaks of food poisoning in which the toxicity had been experimentally demonstrated.† All the strains of staphylococci used in this study fermented lactose and coagulated milk with acid production.

To determine chromogenicity, transplants were made on 1 per cent starch infusion agar so that well-isolated colonies were obtained. The plates were incubated at room temperature (27° to 30° C.) for three days before pigment formation was determined. Toward the end of this study, however, it was found that pigment production could best be observed by growing the staphylococci on milk agar plates. This medium was prepared by adding, aseptically, from a can of evaporated milk,* 10 c.c. of milk to 90 c.c. of melted agar. The agar should be cooled to 50° C. before the milk is added. Pigment production was easily observed on this medium after the streaked plates had been incubated at 30° C. for three days.

To determine hemolytic activity, the staphylococci were cultured on extract agar plates in which 5 per cent defibrinated human blood had been incorporated. The observations were less variable on repeated tests with the use of human blood than with the use of rabbit blood.

The ability to coagulate plasma was demonstrated by inoculating 0.1 c.c. of a twenty-four-hour broth culture of staphylococci into 3 c.c. of diluted human plasma. The diluted plasma was prepared by adding one part of sterile physiologic salt solution to three parts of sterile citrated human plasma. The subcultures were incubated at 37° C. for eighteen hours before readings were recorded.

TABLE I

STRAINS ISOLATED	SOURCE OF STRAINS	NUMBER PRODUCING PIGMENT	NUMBER HEMOLIZING BLOOD	NUMBER COAGULATING PLASMA
19	Clinical lesions	16	16	19
9	Food poison	8	8	9
13	Raw milk	7	7	7
24	Air and dust	6	1	1
65	All sources	37	32	36

Table I shows the results obtained from this study. Thirty-six strains were capable of coagulating plasma. All 19 strains isolated from patients with clinical manifestations of staphylococci infection coagulated the diluted plasma, while only one of the 21 strains isolated from the air and dust showed this characteristic. Another interesting observation was that the food poisoning strains of proved toxicity were all able to coagulate plasma. This reaction on further study with food poisoning staphylococci may prove to be valuable as an exclusion test in the epidemiologic study of such outbreaks. Only three of the 36 strains capable of coagulating plasma were the "albus" variety; one of these was isolated from milk of a cow with mastitis; another from a patient with an infected mammary gland, and the third was a food poisoning strain.

*The evaporated milk used in these experiments was prepared by the Carnation Milk Company.

A number of samples of raw milk were cultured before thirteen strains of staphylococci were isolated. There is a chance that these were more or less saprophytic strains contaminating the milk during its production and distribution. However, two of them were isolated from the milk of a cow with definite symptoms of mastitis. Both of these strains coagulated plasma. It is possible that the other five coagulating strains of staphylococci recovered from raw milk might have been from cows with unrecognized symptoms of mastitis.

All 65 strains of staphylococci were retested for their ability to coagulate diluted human plasma after having been subcultured on extract agar for twelve months. The results obtained showed complete agreement in all cases with the readings made when the staphylococci were first isolated. Blair,³ reporting on the stability of the plasma-coagulase reaction, recorded a 94 per cent agreement on the 102 strains tested between the original and the subsequent tests made two and one-half years later.

CONCLUSIONS

The ability of staphylococci to coagulate diluted human plasma is definitely correlated with its pathogenicity for man.

The ability to coagulate human plasma is apparently a stable characteristic of a strain of staphylococci.

The ability to coagulate plasma may prove to be valuable upon further study as an exclusion test in the epidemiologic study of staphylococci food poisoning outbreaks.

Milk agar prepared by the use of commercially manufactured evaporated milk is an excellent medium for determining chromogenicity of staphylococci.

THE MEASUREMENT OF FORMALDEHYDE FIXATION*

NORVILLE C. PERVIER, PH.D., AND F. LLOYD HANSEN, M.A., MINNEAPOLIS, MINN.

THE fixation of small protein structures by formaldehyde is effected by maceration in diluted formalin with or without suitable addition agents. In embalming, a similarly constituted solution is injected arterially. As the formaldehyde diffuses inward, it unites principally with the terminal NH_2 groups of the protein structures, causing them to set to a more or less rigid gel. The degree of setting, hardness, or fixation of the preserved tissue is a matter of considerable importance, since it is usually desirable to maintain, as nearly as possible, the original consistency and appearance of the tissue. This is especially true in the case of dissecting material and in the embalming of cadavers. Formaldehyde is capable of greatly changing the consistency and gross appearance of tissues when used alone in aqueous solution, and it is, therefore, customary to add to it various other compounds designed to control or to direct its action. These concern mostly preservation and color. The various modifications of the Kaiserling process¹ constitute a case in point.

We have made quantitative studies of many of the physical and chemical factors involved in formaldehyde preservation under a grant from the Minnesota State Board of Health. The present report concerns the quantitative measurement of the hardness of formaldehyde-treated protein structures.

Since no commercial device was available for measuring hardness or rigidity of tissues on a numerical scale, we devised one. This instrument was a modification of one previously used by one of the authors² in other biological studies of physical and chemical factors in biology. In effect it measures the distance through which the surface of the specimen is depressed when a fixed force is applied to a small area of it.

DESCRIPTION OF THE METER

Our meter was adapted from a 3-inch vacuum gauge and is shown in Fig. 1. The flexible ribbon and pipe connection were removed, and a tubular brass sleeve *S*, $\frac{3}{4}$ inch by $1\frac{1}{2}$ inches, carrying three short sturdy prongs *P* at its lower end, was fitted to the case. A $\frac{1}{8}$ -inch brass rod *R* was then fitted to operate smoothly and without extra play within the sleeve. The upper end of the rod was attached to the lever system *L*, operating the pointer, and the lower rounded end of the rod was cut to such a length that it projected $\frac{1}{8}$ inch beyond the plane of the sleeve prongs when the pointer was at zero. A normalized spring was then fitted to retain the rod in the extended position. The strength of the

*From the Minnesota Institute of Technology, University of Minnesota, Minneapolis.
Received for publication, May 31, 1941.

spring was such that a weight of 120 Gm. was required to displace the end of the rod into the plane of the three-sleeve prongs.

Similar devices may be constructed from small pressure gauges, opticians' diopter gauges, or dial reading auto tire gauges. It is essential to have a scale with large well-marked divisions, so that the readings can be taken at a single glance, and the stiffness of the spring must be suited to the range of pliability of the specimens to be measured. The spring which we made and used allowed a scale reading of only one division when the meter was applied to soft living tissues or fresh hog kidneys, and a reading of about 25 on embalmed dissection cadavers.

Fig. 1.—Fixation meter.

USE OF METER

In use, the protruding plunger of the meter is brought perpendicularly against the surface of the specimen and pressed carefully against it until the three-sleeve prongs barely touch the surface. The dial reading is then taken. Several readings over representative areas are taken and the results are averaged. Fleishy areas, which are more or less flat, are to be preferred since underlying bony structures affect the readings somewhat. By choosing like anatomic areas, consistent readings are easily obtained. In cadavers the abdomen and ventral surfaces of the thigh and forearm are preferred, since dependent areas are usually somewhat flattened, distorted, and otherwise changed.

APPLICATIONS

In living bodies the changes in muscle tonus during contraction and relaxation may be measured readily. The changes in tissue consistency accompanying the deposition of fat may be measured. The progress of rigor mortis with time is likewise measurable. The softening of structures following incipient putrefaction also may be followed. We have made hundreds of measurements with this meter upon various subjects, including man, in connection with our quantitative studies on the various phases of action of embalming fluid chemicals.

The time course of the so-called "embalming reaction," which occurs during and after the arterial injection of simple formaldehyde solutions, is shown graphically in Fig. 2. The curves show that the fixation begins when injection starts, increasing very rapidly, but not reaching a maximum until forty-eight hours or more have elapsed. So far as we are aware, no measurements like these have ever been reported, nor has any reference ever been made regarding a

Fig. 2.—Time course of fixation reaction.

delayed fixing or embalming reaction. We believe that such postinjection hardness increases are due to a delayed action in which formaldehyde solutions of decreasing strength diffuse slowly into contact with still unattacked protein structures. Finally, the hardness becomes stabilized, but it may later decrease if the amount of formaldehyde used is so small that putrefaction begins.

The effect of increasing concentration of formaldehyde upon the hardness of tissue is also shown in Fig. 2. The curves represent the first published data upon the subject. All the curves show the time lag already mentioned. It is interesting to note that fixation does not increase directly with concentration. This suggests an adsorption phenomenon, but it may also be due to the "walling-

off" of the solution by local solid areas which interfere with the diffusion of the aldehyde. In time the compound may diffuse through, but then there is less of it. As a result the hardness is less than it would otherwise be. We are continuing the study of this point.

CONCLUSIONS

1. A simple portable meter has been devised for measuring the hardness of tissues, organs, or cadavers on a numerical scale.
2. Changes in the hardness of tissues under varying conditions and modes of treatment can be easily measured.
3. Only a few minutes of experience is needed in order to obtain consistent readings on hardness.
4. The use of the meter does not deface the anatomic structures in any way.
5. The instrument has proved useful in obtaining measurements regarding the synergistic effects of various compounds used in embalming fluids.
6. No numerical data of this kind are to be found in previous literature on the subject.

A SIMPLE AND ACCURATE METHOD OF COUNTING SPERMATOZOA*

ABNER I. WEISMAN, M.D., NEW YORK, N. Y.

THERE are a number of various techniques in present-day general use that are employed in counting spermatozoa in a routine semen analysis. All these methods are complicated either by the use of blood counting pipettes or by the special diluting fluids. The method of Macomber and Saunders¹ involves the use of a blood-counting pipette (1:20 dilution) and a sodium bicarbonate-formalin solution (5 per cent sodium bicarbonate and 1 per cent formalin). The method of Hotchkiss² utilizes a diluent consisting of a solution of saturated sodium bicarbonate together with 1 per cent phenol. The "bulk" method of Belding³ employs larger amounts of semen for dilution, but also makes use of the special Macomber-Saunders diluting fluid.

I use a much simpler method which obviates the necessity of pipettes, blood-counting pipettes, and special diluting fluids. This method is based on a recent report⁴ which showed that plain, ordinary tap water is one of the most drastic

*From the Department of Obstetrics and Gynecology of the Metropolitan Hospital, New York.

spermicides known. The dilution with water serves not only to dilute the sperm cells so that they may be easily counted in a Neubauer blood-counting chamber, but it also causes immediate cessation of motion of the sperms facilitating the count. The use of tap water as the diluent is especially useful to those who have neither the time nor the facilities to prepare special solutions for an occasional semen analysis.

TECHNIQUE

One cubic centimeter of well-mixed whole semen is placed in an ordinary test tube, graduated at 20 c.c. Then ordinary cold tap water is added to the tube up to the 20 c.c. mark.

This simple technique has two distinct advantages: First, by simply adding water all the spermatozoa are killed at once; second, the use of a whole cubic centimeter of semen diluted 1:20 diminishes the error which crops up when using the small amounts of semen usually utilized in the blood-counting pipette technique.

The sperms are counted in the same fashion as are white blood cells, and the final count is arrived at in the following manner: After 1 sq. mm. is counted and rechecked (the sixteen small squares in one corner of the chamber), the number obtained is multiplied by 10 to constitute the number of sperms found in 1 c.mm. This is multiplied by 1,000 to find the number in 1 c.c. of diluted semen. To arrive at the number contained in 1 c.c. of whole undiluted semen, it is now necessary to multiply once more by 20 (the dilution used).

The above multiplication may be simplified by taking the number found in 1 sq. mm. and adding five zeros to it and multiplying by two.

THE USE OF THIOLYCOLLATE MEDIUM IN DIAGNOSTIC BACTERIOLOGY*

ROGER D. REID, PH.D., AND GERTRUDE H. BOWDITCH, A.B., BALTIMORE, MD.

THE use of sodium thioglycollate in infusion medium was described by Brewer in 1940. This medium was described as a fluid medium in which anaerobes could be cultivated without the use of special fermentation tubes or other devices for excluding air. It was also pointed out that the thioglycollate inactivates most of the mercurials commonly used as preservatives in biologic products and is, therefore, useful in testing the sterility of such products. Marshall, Gunnison, and Luxen (1940) have confirmed its usefulness for such purposes. It has been found that this medium is well adapted for the growth of aerobic and micro-aerophilic types of bacteria as well. We have confirmed Brewer's reports and have made extensive use of this medium in routine bacteriologic examinations. After some time we observed that the results obtained by the use of this medium seemed to be better than those obtained with certain others in routine use. A survey of these results revealed the superiority of this medium for certain purposes, particularly in the culturing of specimens of blood and lochia.

This report includes examination of 69 consecutive blood specimens and 93 consecutive uterine specimens. Seven blood cultures were found positive by one or all of the methods used, and 82 uterine specimens were positive by one or more methods.

TECHNIQUE

Blood specimens were, as a rule, planted at the bedside, but if this was not possible, the material was taken directly to the laboratory and placed into the various media within fifteen minutes of the time it was taken from the patient. Five to 10 c.c. of blood were plated directly into 50 c.c. of infusion broth containing dextrose. Duplicate plates were prepared for aerobic and anaerobic incubation, using 1.0 c.c. of the blood specimen in each plate. One cubic centimeter and 2.0 c.c., respectively, were added to tubes of thioglycollate medium. All cultures were incubated at 37° C. and inspected daily for ten days unless growth appeared earlier.

Uterine specimens were brought to the laboratory in Little's tubes wrapped in sterile towels. The contents were transferred to a tube of infusion broth, and inoculations of the various media were made by adding one or more drops of the material to each, depending upon the amount of lochia present. Blood agar plates for aerobic and anaerobic incubation, infusion broth, and thioglycollate medium were used. All media were incubated at 37° C. for ten days before being discarded as sterile, and all were examined daily. When growth appeared

*From the Departments of Pathology and Bacteriology, and Gynecology and Obstetrics, School of Medicine, the Johns Hopkins University, Baltimore.
Received for publication, June 9, 1941.

in broth or in thioglycollate medium, blood agar plates were made to obtain isolated colonies to be fished and studied in pure culture.

It should be noted that in many instances specimens were taken from patients being treated with one of the various sulfonamide compounds. While it has not been our experience (unpublished experiments) that the addition of such substances as p-aminobenzoic acid enhanced the ability of an infusion medium to produce positive blood cultures in such cases, the results that follow might indicate that if such compounds are useful for this purpose, they are to be found naturally in thioglycollate medium.

RESULTS

Of the 69 blood specimens cultured, growth was obtained in only eight. No growth occurred in blood agar either aerobically or anaerobically in ten days. In four cases growth occurred in broth inoculated with 5 to 10 c.c. of the specimen, while growth was obtained in thioglycollate medium in seven cases. In only one instance did growth occur in broth when it did not appear in thioglycollate medium, yet in four cases growth was obtained in thioglycollate medium when it did not appear in broth, although the broth invariably contained from five to ten times as much inoculum. The types of organisms isolated were (1) from broth: alpha streptococci, three times; staphylococci, once; (2) from thioglycollate medium: alpha streptococci, four times; staphylococcus, twice; and pneumococcus, once. Growth appeared in these media as soon as twenty-four hours (in one case), or as late as the seventh day.

Of the 93 uterine specimens cultured, growth occurred on the blood agar plates incubated aerobically in 19 specimens, while those incubated anaerobically gave 16 positive cultures. Broth cultures were positive in 57 instances, and thioglycollate medium gave 82 positive cultures. An analysis of the results obtained with the various media is shown in Table I.

TABLE I

Medium	POSITIVE CULTURES					TOTAL
	9	39	10	7	17	
Thioglycollate medium	9	39	10	0	0	82
Broth	9	0	10	0	0	57
Blood agar plates	9	0	10	0	0	19
(Aerobic incubation)						
Blood agar plates	9	0	0	7	0	16
(Anaerobic incubation)						

According to these data it would appear that thioglycollate medium has a superiority over broth in a ratio of 82:57; over aerobic blood agar plates the superiority is greater, 82:19. Compared with blood agar incubated anaerobically the ratio is 82:16. Since growth occurred in thioglycollate medium in all cases in which growth occurred in any medium when lochia was cultured, and only failed in one case when blood was being cultured—and in this case it is reasonable to assume that the larger inoculum used in the broth is accountable—it appears that thioglycollate medium has an important use in clinical and diagnostic bacteriology. No doubt some of the superiority lies in the fact that anaerobic as well as aerobic bacteria develop well in this medium.

While this paper was being written, *Neisseria intracellularis* (type III) was isolated from the spinal fluid of a case of meningococcus meningitis simultaneously on thioglycollate medium incubated aerobically and chocolate agar incubated in an atmosphere containing carbon dioxide. Isolation was not accomplished on unheated blood agar.

CONCLUSION

The use of thioglycollate medium by itself, or in conjunction with other media, is recommended in routine diagnostic bacteriology.

Since this paper was sent to the publisher this observation has been repeated in 5 additional cases of meningococcus meningitis. In 4 cases type I meningococcus was found, and in one, type II.

MULTIPLE TISSUE WASHER AND PROCESSING ASSEMBLY*

COMBINATION APPARATUS FACILITATING THE PREPARATION OF TISSUES FOR PARAFFIN SECTIONS

F. W. COOK, B.S., M.S., AND G. H. SATTERFIELD, A.B., B.S., M.A., RALEIGH, N. C.

CAREFUL manipulation and preparation of relatively large numbers of tissue blocks as a laboratory routine are possible with a minimum of time, labor, and space with a combination multiple tissue washer and processing assemblies described here. This apparatus has been developed and improved as a matter of necessity for saving time, labor, and space in the course of preparing hundreds of tissues for paraffin sections. Careful consideration was given to histologic principles and methods as well as to the factor of minimum handling of the tissues with instruments.

The cost, availability of materials, and construction of the apparatus were given careful consideration. This apparatus can be constructed by a technician or student assistant with materials from the laboratory stockroom, hardware store, department store, woodshop, and the Kimball Glass Company, Vineland, N. J.

The combined apparatus, multiple tissue washer and processing assembly, is composed of the following parts:

1. Tissue washer: a deep, aluminum pan with 27 outlets and rubber tubes with Hoffman clamps (Fig. 1).

*From the Poultry and Chemistry Departments and Experiment Station, North Carolina State College of Agriculture and Engineering of the University of North Carolina, Raleigh. Aided by a grant from the North Carolina State College Research Fund.
Received for publication, June 16, 1941.

2. Processing assemblies: inverted, open-bottom, screw-cap vials, perforated caps and corks fitting into fruit juice glasses (Fig. 2).
3. Tripod: japanned iron tripod (Fig. 1).
4. Assembly trays: cypress or aluminum (Fig. 1).

The size of the tissue washer, the number of processing assemblies, and the size of the assembly trays will depend chiefly on the requirements of the laboratory. A sufficient number of assemblies should be provided to permit a serial progression of several units of assemblies with tissues through the steps of fixing, washing, dehydrating, clearing, and paraffin infiltrating. In this laboratory, using a tissue washer with 27 tubes, 46 assemblies are used for the first four steps in the procedure and 30 additional assemblies are kept in the paraffin oven for infiltrating the tissues.

The Tissue Washer (Fig. 1).—The multiple tissue washer consists of a deep, 20-gauge, aluminum pudding pan of 6 quarts capacity, perforated with 27 holes jointed to short copper tubes holding 7-inch length rubber tubes provided with Hoffman clamps. The size of the pan and the number of outlets will depend on the requirements of the laboratory. The 27-outlet washer in use in this laboratory has two circular, inner and outer, rows of holes drilled through the bottom of the pan. The outer row contains 18 holes equally spaced. The inner row has 9 holes equally spaced, and each hole is placed opposite one in the outer row. The holes in the inner row should be placed opposite the spaces between the holes in the outer row. The holes are drilled from the outside to the inside. Soft copper tubing, $\frac{1}{4}$ inch outside diameter is cut into one-inch lengths and forced into the holes. These holes are made slightly smaller to hold the tubes firmly in place until jointed with liquid solder. The height of the tubes inside the pan is about $\frac{3}{16}$ inch above the bottom to provide anchorage for the solder. Care is taken that the tubes are perpendicular to the bottom of the pan. Liquid solder is spread around each tube level with its upper end. It is allowed to harden overnight. To further strengthen the support of the tubes in the outer row, which is in a peripheral moat, a ribbon of solder is laid in the moat. Each tube is surrounded by this ribbon of solder. The inner edge of the ribbon reaches the inner rows of tubes, strengthening them likewise. The solder is allowed to harden overnight. The pan is inverted on the tripod, and liquid solder is spread around the copper tubes, strengthening them still more. This tissue washer has been in constant use for more than a year, and not a single tube has loosened or been resoldered. The ribbon of solder in the moat has contracted and drawn away from the wall of the pan, but it has not affected the use of the washer in any way. A rubber tube, 7 inches in length, $\frac{1}{16}$ inch wall, $\frac{1}{4}$ inch bore, is placed over each copper tube, and a Hoffman clamp, $\frac{1}{2}$ inch size, is clamped onto each rubber tube.

This multiple tissue washer possesses the following advantages:

1. It is durable, inexpensive, and easily constructed.
2. It provides a reservoir of water from a single tap for one or 27 assemblies.

3. It provides a constant flow of water, the rate of which is controlled by the Hoffman clamp, and can be regulated to a full stream or to a definite number of drops per minute.

4. It requires only a very small amount of space for operation and storage.

The Processing Assembly (Fig. 2).—The processing assembly consists of an inverted, open-bottom vial, a molded bakelite cap perforated with 5 to 7 holes, a plain 5-ounce fruit juice glass, and two corks, $2\frac{1}{2}$ by $\frac{5}{8}$, and 1 by $\frac{1}{2}$ inches in size. The larger cork fits into the glass container, and has a center hole of a size to hold the vial firmly and upright in place, yet permitting easy shifting of its position in the assembly. The smaller cork is used as a stopper in the

Fig. 1.—Photograph of multiple tissue washer and processing assemblies with assembly tray.

top opening of the vial. The vial, size No. 4, $4\frac{1}{4}$ inches in length, is cut down to a length of about 4 inches. This is accomplished by winding a double loop of a stout cord around the bottom of the vial, and with a see-saw movement of the loose ends of the cord create sufficient friction and heat to cause it to break clean when plunged into ice water. The sharp edges are made smooth by glazing over a Bunsen burner. The molded Bakelite cap is perforated with 5 to 7 holes, the size and number of which will depend on the kind and size of tissues routinely prepared. There should be several perforations in the

cap to permit a free movement of the convection currents into and out of the lumen of the vial, thus assuring a more perfect interchange of reagents between the tissue and the surrounding medium.

The Tripod (Fig. 1).—The iron tripod is of heavy material. The outside diameter of the ring is $5\frac{1}{8}$ inches. The height of the tripod which supports the washer is 9 inches. The diameter of the circle formed by the inner row of tubes on the bottom of the washer should be approximately 7 inches to allow the ring top of the tripod to fit within this circle.

Fig. 2.—Photograph of a processing assembly and its parts. (A) Assembly complete for fixing and dehydrating tissues. (B) Assembly complete for washing tissues. (C) Assembly glass. (D) Glass rod. (E) Small cork stopper for vial. (F) Open-bottom vial. (G) Perforated bakelite cap, for vial. (H) Large cork with center hole for holding vial.

The Assembly Trays (Fig. 1).—The number of assembly trays is dependent on the size of the washer and the number of assemblies used. If only a few are used, a small tray will be satisfactory, but if 27 or more assemblies are used at one time a large tray will be required. Even though the larger number of assemblies is maintained, the smaller tray will be found very convenient when only a few assemblies are in operation. The small tray is a 22-gauge, aluminum layer-cake pan, 10 inches in diameter with a $\frac{3}{4}$ inch hole in the wall to serve as an outlet.

A large tray to hold 27 assemblies was designed and constructed from a single piece of cypress, 2 inches in thickness. It was turned on a lathe to form

a tray with an inside diameter of 14 inches, a rim 1 inch high and $\frac{1}{2}$ inch wide, making a total diameter of 15 inches. There are eight 4-inch legs, $\frac{3}{4}$ inch in thickness, supporting the tray. The tray was designed to be used in a sink.

A second large tray was designed to be used on top of the counter. A wide, shallow "Wear-Ever" aluminum cream pan, No. 401, bottom diameter $14\frac{3}{4}$ inches, top diameter $16\frac{5}{8}$ inches, depth $3\frac{1}{4}$ inches, was purchased from a hardware store. The pan has a single, large outlet, with a rubber tube attached to carry off the overflow water from the assemblies. This outlet was made by drilling through the wall of the pan a hole $\frac{3}{4}$ inch in diameter, $\frac{1}{4}$ inch from the bottom. A piece of copper tubing, $\frac{3}{4}$ inch in diameter, $1\frac{1}{2}$ inches long, was used for the overflow pipe. At one end of the tube a flange was made by making several longitudinal cuts to a depth of $\frac{1}{4}$ inch, and pressing the segments outward. The tube was forced through the hole, and the flange was shaped to the curvature of the wall of the pan. The tube was soldered to the wall, inside and outside, of the pan. After hardening, a rubber tube $\frac{3}{4}$ inch, inside diameter, 1 foot in length, was slipped over the copper overflow pipe.

The durability and practicability of these two large assembly trays have been thoroughly tested and found satisfactory.

ADVANTAGES OF THE PROCESSING ASSEMBLY

The processing assembly is used to carry the tissues through fixation to paraffin imbedding with a minimum handling of the tissues. The principal feature of the assembly is the vial and the perforated bakelite cap, fitting tightly in the center of the hole of the large cork. When this unit is in place, the vial is centered and its distance from the bottom can be changed by shifting its position in the cork. The centering and manipulation of the vial have many advantages.

1. It serves to suspend the tissue in the fixing fluid and permits the penetration of the fixative through all surfaces.
2. It permits thorough washing of the tissue. A rubber tube of the washer is placed inside the vial through the top. A glass rod is placed in the container between the cork and the top edge of the glass.
3. The flow of water through the tube from the reservoir of water is controlled and regulated by the Hoffman clamp.
4. A full stream or only a few drops of water per minute, depending on the character of the tissue, is permitted to flow into the vial.
5. The water circulates in the vial and flows out into the container and over its edge.
6. The glass rod keeps the cork away from one side of the glass, permitting this overflow of water.
7. A continuous flow of fresh water is possible.
8. The loss of the tissue from the vial is prevented as the level of the water inside the vial is below the top opening of the vial.
9. The processing assembly permits the use of calcium oxide and dioxane as dehydrating agents.
10. The vial can be raised above the lumps of calcium oxide.

11. The perforated cap permits the interchange of dioxane and water between the tissue and fluid and the passage of water down to the calcium oxide.
12. The assembly permits dehydration of the tissue with a series of graded alcohols.
13. It permits infiltration of the tissues with paraffin.
14. It permits easy handling of the tissues in the process of imbedding.

A second assembly, kept permanently in the paraffin oven, is used with distinct advantage in this step. The melted paraffin may be kept in the assembly or placed in it prior to transferring the tissue from the first unit. Then the tissue is transferred without handling by inverting the first vial and dropping the tissue into the paraffin in the second vial. The suspension of the tissue in the paraffin allows the paraffin to penetrate into the tissue through all its surfaces, the assembly permits easy handling of the tissue in the process of imbedding. The unit with the paraffin-infiltrated tissue is taken to the imbedding box, and there the tissue is transferred to liquid paraffin in a glass stain jar. The transfer is accomplished by grasping the cork, holding the vial and inverting it, thus avoiding getting hot paraffin on the hands. Occasionally it may be necessary to unscrew the cap to remove the tissue. Placing the tissue in the glass stain jar permits the technician to ascertain its size and shape, thus determining its orientation in the imbedding block. Then the tissue may be transferred to the imbedding block with a perforated spoon.

LIST OF MATERIALS

Capsule vials, screw cap, size No. 4, No. 60957.

Height $4\frac{1}{4}$ inches	$\frac{1}{2}$ gross	\$ 3.75
Black molded caps	$\frac{1}{2}$ gross	1.00

Purchased from Kimball Glass Company, Vineland, N. J.

The prices listed are given only to show cost at time of purchase. The following materials may be purchased from any laboratory supply house, hardware store, department store, and woodshop.

Hoffman clamps, each	\$.20
Tripod	.55
Rubber tubing, per foot	.08
Copper tubing, $2\frac{1}{2}$ feet	.30
Aluminum pudding pan, 20-gauge, 6-quart capacity	1.25
Aluminum layer-cake pan, 22-gauge, 10-inch diameter	.60
Liquid metallic solder, tube	.10
Corks, XXX quality, $2\frac{1}{4}$ by $2\frac{1}{8}$ by $\frac{3}{8}$, bag of 100	10.55
Corks, XXX quality, 1 by $\frac{7}{8}$ by $\frac{1}{2}$, bag of 100	2.35
Assembly tray, cypress	4.50
Assembly tray, aluminum cream pan, No. 401	3.00
Glass rod, No. 6, 10.5 ft.	.25

Approximate cost of tissue washer with 27 outlets:

Aluminum pan	\$ 1.25
Copper tubing and solder	.75
Rubber tubing, 16 feet	1.28
Hoffman clamps, 27	5.40
	\$ 8.68

Approximate cost of 72 processing assemblies:

Fruit juice glasses, 6 dozen @ .40	\$ 2.40
Screw-cap capsule vials, 6 dozen	3.75
Black molded caps, 6 dozen	1.00
Corks, large, 6 dozen	7.56
Corks, small, 6 dozen	1.69
Glass rods, 27	.25 \$16.65
Each assembly: \$0.231

Small assembly tray, aluminum	.60
Large assembly tray, cyprus	4.50
Large assembly tray, aluminum	3.00

Approximate cost of combined apparatus, \$29.48 to \$30.98.

CHEMICAL

BLOOD BROMIDE DETERMINATIONS: THEIR USE AND INTERPRETATION*

M. G. GRAY, PH.D., AND MERRILL MOORE, M.D., BOSTON, MASS.

THE critical level at which symptoms of bromide intoxication appear is the subject of considerable controversy. In addition to its diagnostic value the blood bromide determination has been used in estimating prognosis. This has led to conflicting statements, since many writers have attempted to correlate the symptoms of bromide intoxications with an absolute figure in terms of bromide content of blood and cerebrospinal fluid. Such disagreement is due to the use of chemical methods which do not selectively and accurately determine bromine, and to personal differences among patients which condition the absorption and excretion of bromides. It is the purpose of this paper to present data obtained by the most popular methods, to discuss sources of error and the biochemical and physiologic factors which are pertinent to the interpretation of the blood bromide concentration when used in diagnosis and treatment.

METHODS FOR DETERMINING BROMIDES IN BODY FLUIDS

Bromine is the most difficult halogen to determine, particularly in the presence of others. The exact chemical methods, whether volumetric or gravimetric, require elaborate equipment and laboratory facilities beyond those possessed by most hospitals and skill beyond that of the average laboratory technician. For the most part they require from six to twenty-four hours for completion; the disadvantage of this element is obvious when the results are needed in emergency situations.

Most clinical investigations of blood bromides have been made by adding gold chloride to a protein-free filtrate of serum. If bromide is found beyond that normally present (0.7 to 1.0 gamma per 100 c.c.), there is a color change in the mixture from yellow to brown (or even to brownish red) due to the formation of gold bromide, and the depth of color is proportionate to the concentration. This reaction is inversely analogous to that which occurs in vivo after the ingestion of bromides when the bromide ion is substituted in the body for the chloride ion. The gold chloride reaction was first used by Walter.¹ Walter's method was said to be specific for bromides, but was later shown to be affected by other halogens. Wuth² and Diethelm³ further modified the procedure, recommending it for the diagnosis of bromide intoxication. Diethelm used color tubes containing sodium bromide treated with gold chloride and trichloroacetic acid as standards and with them the comparison was made without optical assistance.

*From the Neurological Unit of the Boston City Hospital and the Department of Diseases of the Nervous System, Harvard Medical School, Boston.
Received for publication, September 30, 1940.

Fremont-Smith, Dailey, and Sloan⁴ compared Walter's method with that of Toxopeus⁵ and found that there were large discrepancies in their results.

Wuth stated in his paper that there was considerable inherent error due to the adsorption of bromide by the serum proteins. This, he claimed, was of the order of 1 to 2 per cent in concentration of 25 mg. per 100 c.c., and from 11 to 14 per cent in a concentration of 200 mg. per 100 c.c. Katzenelbogen and Goldsmith,⁶ who used modifications of the Walter test, experienced difficulty in matching the standard gold bromide with that in the serum. They attempted to obviate this by adding sodium chloride to the standard solution.

Without question the gold chloride method determines bromides, but, in addition, it may determine other substance as well, and thereby lose one of the chief values of a chemical examination, i.e., specificity.

Yates'' procedure is probably the simplest accurate method which does not require equipment beyond the scope of a good clinical laboratory. A protein-free preparation of the material being analyzed is placed in a nickel crucible with 25 per cent potassium hydroxide and evaporated to dryness. It is heated in an oven at 500° C. for twenty minutes, then cooled to 18° C. Sulfuric acid is added slowly, followed by a chromic-sulfuric acid mixture. Potassium iodide and starch solution are added, and the mixture is then aerated for five hours. At the end of that time, it is titrated with N/1,000 sodium thiosulfate. We have obtained consistent results and excellent recoveries with this method.

EXPERIMENTAL PROCEDURE

In the course of routine bromide determinations we have observed that the gold bromide reaction is subject to considerable error and, in spite of its simplicity, the potential error is enormous. Our experiments were devised to ascertain whether the gold chloride method would (1) yield duplicate results on the same material, (2) negative results in the absence of bromine, and (3) recover added bromides from serum. The effect of varying serum protein concentrations and of varying the bromide concentrations with respect to protein adsorption was also studied.

The procedure for blood bromide determinations followed in our experiments was that suggested by Diethelm, but three quantitations were made on each specimen of blood, employing for standard comparison (1) color tubes containing various dilutions of sodium bromide treated with gold chloride and graduated at intervals of 10 mg.; (2) a Bausch & Lomb visual type colorimeter, using standard solutions of gold bromide containing 1 or 2 mg. of sodium bromide per cubic centimeter according to the expected concentration of bromide in the unknown solution, and (3) a photoelectric comparator which had been standardized with ten solutions of sodium bromide treated with gold chloride. Using this apparatus, it was possible to refer all bromide concentrations to a single standard. The standard solutions were checked by the method of Yates for accuracy. The mean error in them was ± 0.78 per cent. The bloods were filtered after being treated with trichloroacetic acid to remove proteins. There were added to the filtrates, 0.5 per cent gold chloride in the proportion of 0.2 c.c. to each 1 c.c. of filtrate.

A series of bloods known to contain increased amounts of bromides were examined by the foregoing procedures. The findings were compared to determine whether it is possible to obtain duplicate values on the same specimen and to learn the error between several methods of comparing unknown concentrations of gold bromide with standard concentrations. The blood specimens were obtained from voluntary subjects of other experiments, who received sodium bromide by mouth and no other medication for periods ranging from ten days to six weeks. The ordinary diet with customary sodium chloride was eaten. Two determinations by each method were done, and each specimen was quantitated by the three methods described. The data from 20 specimens are presented in Table I, from which it can be seen that the visual comparison of gold chloride treated blood filtrates with color tubes is accompanied by considerable error. This is chiefly due to the impossibility of matching colors closely by this means, and in part to the fact that our color tubes represented intervals of 10 mg. of bromide. Using these tubes, closer intervals than 5 mg. could not be approximated by the eye. The range of values found by visual comparison under standardized illumination was from 20 to 155 mg. per 100 c.c., and the average difference between two determinations on the same serum was 19.8 per cent. The maximum difference was 37.5 per cent and the minimum was in one case 0.

When a Bausch & Lomb colorimeter was used for comparison, the bromide values could be estimated more closely. The range of concentration was from 21.4 to 156.4 mg. per 100 c.c. A number of specimens could not be matched exactly with the standard, appearing to be slightly off-color (Katzenelbogen and Goldsmith⁶). The average difference between two determinations was 6.1 per cent, the maximum 19.8 per cent and the minimum 0.4 per cent. Thus the use of the colorimeter reduced the error considerably, but the analyst is frequently confronted with bloods in which a comparison is very difficult or impossible even with this optical assistance. Except for the badly matching filtrates, the difference was 5.5 per cent or less, which limit is a considerable error for exact chemical determinations, but is much more acceptable than the values obtained by direct visual comparison.

The use of the photoelectric colorimeter further reduces the variation between two determinations on the same blood. The average difference in the twenty bloods reported here was 0.7 per cent. The maximum difference was 2.3 per cent and the minimum was 0. For clinical purposes this instrument offers relatively little advantage over the Bausch & Lomb colorimeter, but it entirely eliminates the individual factor in making comparisons; it allows reference of all specimens to a single standard and permits many determinations to be made in a very short time.

However, the close agreement between some of these determinations when made by colorimeter may be misleading, since in many laboratories the only criterion for control of a method is that it shall yield comparable results on the same material. The possibility of chlorides and other substances being determined along with bromides is not ruled out when such a criterion is used.

With respect to the use of prepared color tubes for comparison, as in Diethelm's procedure, it is probable that the error would be greater than that observed by us, since the intervals recommended are greater than 10 mg. at many points.

INFLUENCE OF SUBSTANCES OTHER THAN BROMIDES

A number of bloods were taken from patients who had been hospitalized for a long time and who had not received any bromide medication. These were subjected to the specific qualitative test of Belote,⁸ and a gold chloride determination was made. As far as possible bromides were ruled out of the immediate past history of these individuals, either from the hospital record or from their own statement. Among the 76 bloods examined were several from reliable voluntary subjects who disclaimed bromide ingestion for six months or longer before the blood was drawn. Of this series no blood gave a positive qualitative eosin reaction, but 9 showed from 16 to 53 mg. of bromide by the gold chloride method. Two patients took no medication of any sort for four and six months, respectively, and the other 7 received various substances. Among the medication received by the patients who appeared to have increased blood bromides were the following substances: cysteine, diphenylhydantoin, liver extract, caffeine sodiobenzoate, wine of Bulgarian belladonna, thyroid, pituitary extract, and physiologic saline solution.

It is difficult to explain the positive findings in these cases unless the gold chloride reaction is nonspecific. It has been pointed out by Johnson and Partlow,⁹ Tod,¹⁰ and Katzenelbogen and Czarski¹¹ that chloride and iodides interfere with the reaction; this may explain the findings in several patients. If it is true that the gold chloride reaction is nonspecific, levels at which toxic symptoms appear must be disregarded, since some of the so-called blood "bromides" in many cases may actually be due to nonbromide material. Thus the use of the gold chloride reaction to follow the bromide treatment of epileptic patients with bromides may be fallacious.

To corroborate the positive findings in patients with blood bromides who had not been ingesting bromides, the medication which they had been receiving was added to bromine-free blood sera (1:20,000) and gold chloride tests were made. Diphenylhydantoin, pituitary extract, thyroid, potassium iodide, and Lugol's solution gave negative results by the eosin test, but produced slight degrees of color after gold chloride was added. The color produced was not adequate for comparison with a standard by a colorimeter, but the observation suggests that the gold chloride reaction is nonspecific for bromides.

ADSORPTION OF BROMIDES BY BLOOD PROTEINS

If we assume that the error which tends to lower the bromide values is chiefly due to protein adsorption, it would seem probable that the higher the concentration of proteins in the serum, the more adsorption would occur. Twenty bromine-free sera to which sodium bromide in concentrations varying from 25 mg. per 100 c.c. to 600 mg. per 100 c.c. had been added were examined. The total serum proteins were determined by the method of Greenberg;¹² the bromide concentration was determined by the Yates method and by the gold chloride method.

*These bloods could not be matched easily with standard.

It was found that the protein concentration has little relation to the amount of bromide recovered, since the values were almost evenly distributed with respect to the mean protein value and the mean bromide recovery value.

When recovery values were plotted against bromide concentration, it appeared that the higher the concentration the lower was the recovery of bromides from serum by the gold chloride method. Thus, it could seem that the error is greatest when exact information is most important due to the critical implications of high bromide values. No marked effect on the gold chloride method was observed by altering the acidity of either unknown or standard solutions within the limits which might be expected in the course of an ordinary determination.

DISCUSSION

The use of methods which give only an inaccurate estimate of the bromine concentration is unfortunate. The gold chloride method is not accurate, and its use for the initial diagnosis of intoxications may be adequate, but a simple, accurate method is needed for use in prognosis and in following treatment. It must be employed before an attempt to correlate the symptomatology with blood concentrations in bromide intoxication can be made.

This oversight may lead to more serious confusion than already exists. As a medicolegal test the value of the gold chloride method would be seriously questioned but the failure to consider individual variations in the ability to handle bromides is possibly more serious than the inaccuracies of the method. The danger of confusing bromide intoxications with other conditions has been pointed out frequently, but no one has expressed concern over confusing other stuporous conditions with bromide intoxication and administering large amounts of salt. We should consider the folly of giving 20 Gm. of salt daily to a person who has suffered head trauma and who has taken bromides to relieve the pain of a concussion or a subdural hemorrhage, or to one who is suffering from coma of renal origin. Elevated bromide contents in the blood are often found superimposed upon more serious conditions resulting from entirely different etiology.

In dealing with conditions in which bromides are represented, the determination of urine and blood chlorides, along with bromides, is a far better indication of the progress of treatment or of the validity of a diagnosis of bromide intoxication than isolated blood bromide determinations, but the clinical condition of the patient is more important than any laboratory finding. It is not our belief that blood bromide determinations should be abandoned, but rather that more accurate methods should be employed and that the limitations of laboratory findings should be recognized.

SUMMARY

Blood bromide concentrations are usually determined by a reaction in which gold chloride is added to a protein-free filtrate of serum, and the resulting colored substance is compared with quantitative standards. Most of the exact bromide methods are difficult and are beyond the scope of hospital and clinical laboratories. The gold chloride method has been examined critically, and sources of error are described. It is possible to obtain almost duplicate results

with some modifications of this method, but this is misleading, since it causes unwarranted faith to be placed in the results regardless of other sources of error. The use of a colorimeter can reduce the error considerably, but it has been our experience that it is appreciable. The reaction is probably not specific for bromides, since other chemically unrelated substances may cause a positive reaction. The concentration of blood bromides appears to be more important than the serum-protein concentration as a source of error. There have been reported anomalous findings of persons with extremely high blood bromides who showed no toxic symptoms, and of others who have demonstrated extreme bromide intoxication while the blood bromide was low, which may be related to the method used. The comparison of chloride and bromide levels in blood and urine is more valuable than isolated determinations of the blood bromide. Such data should be used as presumptive evidence. The clinical condition of the patient is a more valuable diagnostic and therapeutic index.

STUDIES ON MELANURIA*

STEPHEN ROTHMAN, M.D., CHICAGO, ILL.

MELANURIA usually occurs in the final metastasizing stage of malignant melanomas. In the urine a colorless or light-colored precursor of melanin, a water-soluble melanogen or chromogen, is excreted which in the presence of oxygen is readily transformed into the dark melanin precipitate. The usual laboratory tests to detect melanuria are based on this fact. An oxidizing agent is added to the urine, and the subsequent darkening is taken as a sign of melanuria. The recommended oxidizing agent is ferric chloride. As a second test bromine water is used. Most biochemical and clinical laboratory manuals and textbooks do not mention tests other than those for detection of melanin precursors. These tests, however, are neither sensitive nor specific, and they yield highly confusing and inconsistent results, as pointed out by Blackberg and Wanger in 1933.¹ Ferric chloride may form dark brown precipitates in normal urines if they are alkaline, and falsely positive results also can be obtained if drugs are excreted in the urine. Furthermore, these tests are hardly more sensitive reactions than the simple darkening of the urine exposed to air.

And yet, more sensitive and more specific qualitative chemical tests for the detection of melanogen have been known since 1887. In that year Thormählen² described the reaction which has been named after him, and which in our laboratory was found to be about 50 times as sensitive as the oxidation tests. So far the Thormählen test has never been found to be positive in the urine in any condition other than melanuria.

This test is performed in a manner similar to the Legal test for acetone, although it has no relation to it. A few drops of diluted solution of sodium nitroprusside are added to 3 to 5 c.c. of the urine, and then a few drops of a strong alkali solution. In our experience 10 per cent sodium hydroxide solution is the best alkalizing agent, better than ammonia or caustic soda. By alkalization a deep ruby color results. This color is not characteristic for the melanogen. It is also formed by acetone and by creatinine. But if one acidifies with glacial acetic acid an azure blue color immediately appears which is specific for the melanogen. By addition of glacial acetic acid acetone turns deeper red; creatinine becomes yellow, then slowly green, and finally blue. Of course, Thormählen's test can be considered positive only if, through acidification, the color suddenly changes to blue.

Another even more sensitive, but less specific, test is Ehrlich's aldehyde reaction, which is known as the urobilinogen test. There is evidence that the

Received for publication, November 10, 1911.

positive Ehrlich reaction in melanuria is not due to the simultaneous presence of urobilinogen. The urobilinogen reaction disappears from the urine after its exposure to air for a short time (maximum after two hours), whereas in melanuria the test remains positive as long as does the Thormählen test, usually for several days. In fractionating the urine by different precipitation methods, the Ehrlich test is positive in those fractions which contain the melanogen, and negative in the others. Even preparations of melanogen which are purified chemically to a high degree are Ehrlich positive.³

The Ehrlich test was found in our laboratory to be about twice as sensitive as the Thormählen test. Therefore, melanogen may be detected with Ehrlich's reagent when the Thormählen reaction is still negative. However, in such a case the Ehrlich reaction as an indication of the presence of melanogen must be verified by concentrating the urine and then demonstrating a positive Thormählen test. In any case, the positivity of both reactions indicates the presence of melanogen with absolute certainty.

Fig. 1.—Formation of melanin precursors (Raper⁴).

It has been known for a long time that Thormählen's reaction is given only by indole and its derivatives. However, the origin of the indole compounds in the melanotic urine was not understood until Raper⁴ in his fundamental work traced step by step the chemistry of melanin formation from tyrosine. Before that it was an accepted assumption that the source of the "Thormählen substance" is tryptophan as the only natural indole compound in the protoplasm.⁵

Raper presented evidence that indole derivatives are formed from tyrosine in the course of melanin formation, and it seems today that the only source of melanin pigment in the whole animal world is tyrosine.

In the course of oxidation of tyrosine to melanin by tyrosinase⁴ or by ultra-violet light^{5, 7} the first step is the formation of dihydroxyphenylalanine, or by abbreviation "dopa" (Fig. 1). The next step is the formation of a ring by the alanin side chain so that an indole nucleus results which is a condensed benzene and pyrrole ring. In 1935 Linnel and Raper³ presented strong supporting evidence that the melanogen is the monopotassium salt of 5-6 dihydroxy-indole. In acknowledging the findings of Raper it became easy to understand that in addition to the indole derivatives, catechol compounds also (derivatives of dopa) were found as melanin precursors in melanotic urine.^{8, 9}

EXPERIMENTAL

Most experiments were carried out with the urine of a 67-year-old patient from the service of Dr. George F. Dick. The patient presented the usual history of persons suffering from malignant melanomas. His left eye had been enucleated one year ago. He was admitted, very ill with jaundice and liver enlargement. His urine had been dark for several weeks. Only about three liters of this patient's urine could be collected since he was suffering from incontinence, and the daily urine obtained averaged 300 c.c. daily for ten days, after which time he died. Permission for autopsy was not obtained.

One urine specimen of another patient with a similar history was supplied by Dr. M. H. Ebert from the Rush Medical School, Chicago. This specimen amounted to only 70 c.c.

The material was first used for estimating the sensitivity of the different melanogen tests. This estimation was carried out by serial dilution of the urine with water and estimation of the threshold dilutions at which the reactions became negative. As mentioned in the introductory remarks, it was found that Thormählen's test was 50 times, and the Ehrlich test was 100 times, as sensitive as the ferric chloride test.

The material was used for answering two other clinically important questions: (1) Whether by simple methods the melanogen can be differentiated from indole and indican; and (2) whether the melanogen can be concentrated by fractionation of the urine so that smaller amounts may be detected in the fraction than is possible in the whole urine.

1. The qualitative chemical differentiation of the melanogen, indole, and indican was possible by applying the common laboratory tests for indole derivatives. As shown in Table I it was found that urine containing large amounts of indican does not give the Thormählen, Ehrlich, and Herter indole reactions, and vice versa. The melanogen does not react with Obermayer's and with Jolles' reagents. Indole itself displays the same color reactions as the melanogen, but with one remarkable exception: Herter's reaction most sensitive for indole is negative in the melanotic urine. This is an expedient to differentiate indole from the melanogen.

2. Concentration of melanotic urine for clinical purposes was carried out by Blackberg and Wanger,¹ but their method was based on the oxidation of

melanogen to melanin and not on the sensitive color reactions of indole. Fractionations for purposes of chemical identification of the melanogen were made by several authors.^{3, 9, 10}

Testing all recommended methods of fractionation we found that the simplest and most effective method was precipitation with lead acetate.

TABLE I

QUALITATIVE COLOR TESTS OF INDOLE AND ITS DERIVATIVES OCCURRING IN THE URINE

TEST	INDOLE	INDICAN	MELANOGEN
Herter's naphthoquinone test	+	-	-
Ehrlich's aldehyde test	+	-	+
Thormählen's test	+	-	+
Nitroso-indole test	+	-	+
Obermayer's test	-	+	-
Jolles' test	-	+	-

The fresh urine was acidified with acetic acid to a pH of about 4.5, and lead acetate was added. The precipitate containing phosphates and sulfates was discarded. The clear filtrate, then, contained the total amount of melanogen. If this filtrate was alkalinized with ammonia to about pH 8, the newly formed lead precipitate took down most of the melanogen. After sharp centrifugation and separation from the supernatant fluid, the precipitate was ground up in small amounts of water. The suspension was decomposed by introduction of hydrogen sulfide. The precipitated lead sulfide was removed by filtration; the excess hydrogen sulfide by cautious heating. The clear yellow filtrate contained three to ten times as much melanogen as the original urine had in the same volume.

ADDITIONAL OBSERVATIONS

1. In the fractions obtained by precipitation with lead acetate the melanogen proved to be much more stable than in the original urine. Positive Thormählen and Ehrlich reactions could be demonstrated in these fractions after the samples were refrigerated in the dark for four months, covered with a cork stopper only, unprotected against oxidation. Obviously this stability of the melanogen was not due to the acidity of the fractions (pH 5) because an even better protection of the melanogen was obtained with barium hydroxide in slightly alkaline medium.¹⁰ It seems rather that any kind of fractionation, consisting of rough chemical procedures, removes or inactivates a component of the urine which accelerates the oxidation of melanogen to melanin. It may be assumed that this factor is the enzyme of melanin formation which is present in pigmentary malignant tumors^{11, 12} and which could be spilled over in the urine together with the melanogen.

2. Dr. F. K. Oldham, of the Department of Pharmacology, using hypophysectomized frogs as test objects, demonstrated melanophore activity in our melanotic urine samples. Earlier experiments with similar results were carried out on animals which were not hypophysectomized.^{13, 14} However, this assay is reliable on hypophysectomized frogs or fishes only.¹⁵ Roughly concentrated fractions of the melanotic urine had no darkening effect on the hypophysectomized frog.

3. The originally light yellowish acid urine fractions with high melanogen content turned brilliant red on standing in the icebox. Similar observations were made as early as 1890,¹⁶ and a contemporary thorough chemical study of the red substance in melanotic urine was made in 1936.⁹

Chemical and spectrographic analysis of the red pigment in our laboratory showed that it is similar to the acid-soluble red pigment of human hair, first described by Arnow in 1938,¹⁷ but is not identical with it. The detailed results of these experiments will be described elsewhere.

DISCUSSION

The fact that melanogen does not show indican reactions and that indican does not give positive indole reactions is in accord with the statement of Böhm.¹⁸ In 1939 Böhm, in a different way, reached the conclusion that indigo blue formation, on which the indican tests are based, occurs only in those indole derivatives which have substituted C atoms on the pyrrole ring so that they can react there. The 5-6 dihydroxy-indole compound of Raper can react on the fifth and sixth C atom of the benzene ring but not on the pyrrole ring, and, therefore, does not yield indigo blue on oxidation (Fig. 2).

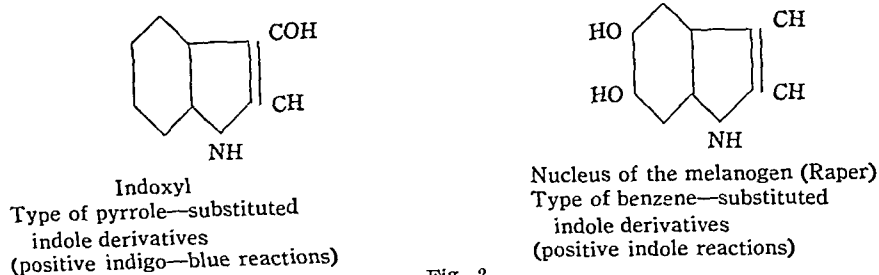

Fig. 2.

The unexpectedly negative Herter reaction of the melanogen which we obtained has not been previously reported.

By the concentration method described above, the test for melanuria has been rendered up to ten times as sensitive as is the Thormählen test and up to 500 times as sensitive as is the ferric chloride test in the original urine. It seems probable that the diagnosis of melanuria can be made considerably earlier in this way.

It has been claimed^{1, 5} that the urine becomes dark only after the liver has been involved to a considerable degree in the metastatic process so that a functional insufficiency of the liver results. If this were true, if the melanuria indicated marked liver damage rather than growth of melanotic tumors anywhere in the body, there would be little hope of discovering the melanuria in an early state by concentration methods. However, there is strong evidence against this theory. By feeding indole derivatives which are not substituted on the pyrrole ring to normal animals and normal human beings, melanuria can be easily provoked, which is chemically identical with pathologic melanuria following malignant pigmentary growth.¹⁸ Thus melanuria can be provoked in normal organisms without actual liver damage. It seems that melanuria depends only on the amount of melanogen present in the body. If this amount exceeds the threshold, either as a result of feeding or as a result of the metabolic process

in the tumor, melanogen is excreted through the kidneys. There is no reason to assume that exceeding of the threshold occurs suddenly with spilling over of large amounts of melanogen from the beginning. It is more probable that there is a gradual overstepping of the threshold similar to the case of glycosuria or indicanuria. In this case "latent melanuria" may precede macroscopically obvious melanuria by weeks or months. Therefore, in patients who are thought to have melanotic tumors, the *concentration method as described above* might be useful for an early diagnosis.

SUMMARY

1. The melanogen of melanotic urine can be differentiated from other indole compounds occurring in the urine by simple qualitative chemical tests.
2. By the use of Thormählen's and Ehrlich's reactions in a urine suitably concentrated, the test for melanuria can be rendered 500 times as sensitive as it is with the ferric chloride test in the original urine.
3. By rough chemical fractionation the melanogen becomes more stable than it was in the original urine.
4. The melanotic urine has melanophore activity which disappears after rough chemical treatment.
5. The red pigment formed in melanotic urine after acidification and the pigment of human red hair have similar properties.

A RAPID METHOD FOR THE DETERMINATION OF SERUM PROTEIN*

R. A. MORTENSEN, PH.D., LOMA LINDA, CALIF.

MANY indirect methods, designed to replace the time-consuming Kjeldahl procedure, have been proposed for the determination of serum protein. These have been reviewed by Peters and Van Slyke,¹ who conclude that the specific gravity method is the most reliable. This makes use of the linear relationship which exists between the specific gravity of the plasma or serum and the total protein content. The existence of such a relationship for human plasma was first demonstrated by Moore and Van Slyke.² Weech, Reeves, and Goettsch³ then used dog's serum and found an even closer correlation. Kagan⁴ examined specimens of human serum and derived an empirical relationship differing only slightly from those previously reported.

For determining the specific gravity, Moore and Van Slyke used a small pycnometer and an analytical balance. The falling-drop technique of Barbour and Hamilton,⁵ developed previously, offers the advantage of being rapid as well as accurate; but the apparatus is relatively complex, and considerable experimental skill is required for its operation. Bing⁶ described a method in which serum is diluted with measured amounts of 0.9 per cent sodium chloride until it acquires a specific gravity corresponding to 3.0 per cent protein, as indicated by an accurately adjusted float in the form of a glass bead. Instead of a single bead Simeone and Sarri⁷ employed twenty-one glass beads made at random in large numbers and carefully selected according to their densities so as to form a graded series covering the range of serum protein values. In use, these beads were immersed in the serum, one at a time, until a bead was found with a specific gravity approximately equal to that of the serum.

The present paper describes a specific gravity method for the determination of serum protein which is both rapid and accurate. The essential apparatus consists of a single article of glassware of relatively small dimensions which can be calibrated to read directly in either specific gravity or protein content. Only ordinary glass-blowing skill is required for its construction.

METHOD

The apparatus consists of a specially constructed pipette (Fig. 1b), containing two hollow glass heads. One bead is slightly lighter and the other is slightly heavier than the range of sera to be examined. In use, the pipette is filled with serum and placed in an upright position, the beads coming to rest at points *k* and *k'*. It is then closed and inverted by rotating 180 degrees.

*From the Department of Biochemistry, School of Medicine, College of Medical Evangelists, Loma Linda.

Received for publication, November 11, 1941.

After inversion the lighter bead will move upward while the heavier one descends, the ensuing collision occurring at a point which is determined primarily by the specific gravity of the liquid contained in the pipette. By observing the position of this point with reference to a properly calibrated scale engraved on the tube (Fig. 1*d*), the specific gravity of any sample falling within the range covered by the beads can be found.

In filling the pipette it is convenient to use a suction tube, into which a snugly fitting solid glass bead has been inserted. Using the bead as a valve in the usual way, the liquid can, with ease, be drawn up into the pipette and retained while a rubber band is stretched over the tip. The suction tube is then removed and the closure is completed after the manner of blood pipettes. The trap, *t*, is designed to catch air bubbles. The form shown in Fig. 1*a* does not require a rubber band, and air bubbles, if present, are removed through one of the stopcocks. In use, this type of pipette is not filled completely; a small amount of air is left in the capillary below the upper stopcock in order to permit expansion of the liquid. The capillary must have sufficient length to serve this purpose.

Rotation of the pipette is facilitated by use of a holder, arranged so that it may be turned through 180 degrees in a vertical plane. This consists of a light metal frame provided with a spring clip for holding the pipette, and is mounted on a horizontal axle, which in turn is supported on a base equipped with leveling screws. Movement of the frame is limited to 180 degrees by means of stops. For ordinary measurements, however, satisfactory results are obtained simply by inverting the pipette while it is held in the hands.

No particular size of pipette is required. Capacities of 1 or 2 c.c. have been found to be satisfactory. The bulb is made of standard wall tubing having an internal diameter of about 4 mm. and a length of 80 mm. in the case of the 1 c.c. pipette, and 5 mm. and 100 mm. for the larger size. The capillary stems have a bore of approximately 1 mm., with the exception of the portion immediately below the trap, which is blown out to about twice this size in order to permit freer passage of air bubbles into the trap. The diameter of the beads is somewhat less than one-half that of the tube in which they are enclosed. It is well to have them as nearly equal in size as possible. This is accomplished by preparing a number of beads and matching them according to size with the aid of a low-power microscope provided with a micrometer eyepiece.

The beads are blown from thin-walled, capillary, pyrex tubing. The desired density is obtained by collecting a small lump of glass on one end and grinding off a little at a time until the bead neither sinks nor rises rapidly when placed in a solution of potassium sulfate of predetermined specific gravity. It is then returned to the flame where the remaining portion of the lump is fused into the main body of the bead. When made in this way, a bead will, in general, have a thick wall at one end; but this is not detrimental to its usefulness. Final adjustment, if necessary, may be made by grinding the thick end. The ground area is fire-polished in a small flame at a relatively low temperature. This procedure not only gives a much higher yield of useful beads than mere random methods, but also results in a considerable saving in time.

The walls of the tube are indented at k and k' by heating the glass in spots 120 degrees apart, and pushing inward with a thin brass tool. These indentations provide seats in which the beads are brought to rest in the center of the tube. Considerable care is required in making them so as to reduce the area of contact to a minimum, and also to allow sufficient space for the liquid to pass freely around the bead at the beginning of an excursion.

Fig. 1.—Specific gravity pipettes. *a*, With stopcocks; *b*, for rubber band closure; *c*, inverted, showing displacement of glass beads; *d*, graduated to read in specific gravity, figures representing second and third decimal places. Reading shown is 1.0268, corresponding to a serum protein content of 6.8 per cent. *e*, Scale for pipette (*d*) reading directly in percentage of serum protein; *f*, direct reading protein scale constructed from calibration curve in Fig. 2, $K' = 0.96$.

THEORY

When a small sphere falls under the action of gravity through a viscous fluid, the resistance increases with increasing rate of fall until it is equal and

opposite to the effect of gravity. Thenceforth, it has a constant velocity, for there is no resultant force acting upon it. This velocity is given by the well-known Stokes' law as

$$v = \frac{2g \alpha^2 (d-D)}{9\eta} \quad (1)$$

where d is the density of the sphere, D the density of the fluid, η the coefficient of viscosity of the fluid, and α the radius of the sphere.

Stokes' law as given applies only to a spherical body falling through a fluid of infinite extension, but the velocity of a small sphere falling axially through a viscous liquid in a cylindrical tube may be expressed by the modified form

$$v = \frac{K (d-D)}{\eta} \quad (2)$$

K being a numerical constant for a particular tube. Then, replacing the velocity by its equivalent S/t , where S represents the distance traversed in the time, t , and applying the resulting formula to the motion of each bead in turn, two equations are obtained which may be combined to give the relation

$$\frac{S_1}{S_2} = K' \frac{D-d_1}{d_2-D} \quad (3)$$

where S_1 and S_2 are the distances traveled at constant velocity before collision by the light and heavy bead, respectively, and d_1 and d_2 are their densities. The value of K' is constant for a given apparatus, and is equal to unity when the two beads have the same effective radius. Since both beads are accelerated at the start in the same manner and reach their limiting velocities within a comparatively short distance, S_1 and S_2 may be taken to represent the entire distances traversed without introducing significant error.

An exact expression should take account of the repellent force exerted by one bead upon the other as the point of collision is approached. It can be shown that both are affected by this factor to the same extent only when their velocities are equal. Another factor is the "end effect," i.e., the effect of the ends of the tube on the velocity. The complete analysis, however, presents an involved problem in hydrodynamics.

Although formula (3) is obtained by an approximate treatment, it is sufficiently accurate to be used for purposes of calibration. It was tested in an extended series of experiments using matched beads of various sizes and densities in solutions of potassium sulfate as well as in serum, and found to hold, within rather narrow limits, over a wide range of fluid specific gravities. Typical results are shown in Fig. 2. It will be seen that the greatest deviations occur in the case of extreme values. None is of sufficient magnitude, however, to be of practical importance. It may be said that the accuracy with which the equation fits experimental values justifies the assumptions used in its derivation.

CALIBRATION

If the densities of the beads are known, a pipette may be calibrated by taking a single collision point reading on serum or a salt solution of known specific gravity. The reading should fall near the midpoint of the bulb, since

in this case errors of reading and inaccuracies in the formula will have a minimum effect. The beads are most conveniently calibrated, before being sealed in, by matching them with solutions of potassium sulfate and subsequently determining the specific gravities of the solutions with a pycnometer. With d_1 and d_2 thus found together with values for S_1 and S_2 , the constant, K , in equation (3) is computed. Having evaluated K , it is possible to calculate the distances, S_1 and S_2 , for any specific gravity lying within the range of the beads.

Fig. 2.—Typical calibration curve. Readings represent distance, S_1 , traversed by light bead. Curve was drawn from points computed by equation (3) from bead densities and one collision point reading. Crosses indicate solutions of potassium sulfate; circles denote serum modified by dilution or evaporation.

A more direct method of calibration may be used in which collision point readings are taken on a series of standard solutions. Each point is marked with ink or a sharp wax pencil, and its distance, S_1 , from the end of the bulb is measured by direct comparison with a millimeter scale. The specific gravities of the solutions are then plotted accurately on coordinate paper against the readings, S_1 , and a smooth curve is drawn through the points. For ordinary work a curve based on four or five well-spaced points should suffice.

The two methods are compared in Fig. 2. It may be pointed out that the first method does not require the drawing of a curve. Regardless of which method is followed, a scale is readily constructed to read directly in specific gravity (Fig. 1*d*). Calibration in terms of percentage of protein is made with the aid of the empirical formula of Weech, and co-workers.³ Integral protein percentages are substituted in the formula, and the corresponding specific gravities are calculated. The latter may be used in either of the foregoing methods for preparing a direct reading scale such as shown in Fig. 1*e*.

TEMPERATURE CORRECTION

In order to determine the influence of temperature, a pipette calibrated at 20° C. was filled with human serum and placed in a thermostatically controlled water bath so arranged that any predetermined temperature could be maintained within one-twentieth degree. Specific gravity readings were taken at intervals of five degrees, from 15° to 35°, with results as shown in Table I. Within the limits of experimental error the readings follow the thermal expansion of serum, indicating that the change in density of the serum is the only important factor involved. The expansion of the pyrex glass beads is about one-twenty-fifth that of serum and may be disregarded in dealing with a relatively narrow temperature range.

TABLE I
EFFECT OF TEMPERATURE ON PIPETTE READING

TEMPERATURE, °C.	SPECIFIC GRAVITY	PROTEIN (GRAMS PER 100 C.C.)
15	1.0310	8.3
20	1.0300	7.9
25	1.0288	7.5
30	1.0274	7.0
35	1.0258	6.4

It follows that a pipette which is calibrated at 20° C. and used at a temperature, t° , will read in specific gravity at $t^\circ/20^\circ$ C. Between 20° and 30° the change in serum specific gravity averages about 0.00025 per degree centigrade. A reading taken within this temperature range may be reduced to specific gravity 20°/20° C. by adding 0.00025 to the observed specific gravity for each degree centigrade above 20. Such correction is accurate within one unit in the fourth decimal place. For clinical purposes an approximate correction may be applied by adding 0.1 to the percentage of protein for each degree rise in temperature.

RESULTS

In order to test the accuracy as well as the clinical practicability of the method, measurements were carried out on a large number of serum specimens, and the results were compared with those obtained by the pyknometer and falling-drop methods. A 2 c.c. pyknometer of the Nicol type provided with a graduated stem was used. This was found to be superior to the specific gravity bottle of Moore and Van Slyke² in accuracy, and ease of filling and cleaning. The falling-drop method followed the technique described by Barbour and Hamilton.⁵ The blood samples were obtained by venepuncture from patients selected in most cases because they were known or believed to have abnormalities in their serum proteins. Typical results are summarized in Table II. Total protein estimations by the macro-Kjeldahl method are included for comparison.

Undoubtedly the pyknometer method is the most reliable one available for the determination of specific gravity. The average difference between the results obtained by the pyknometer and the specific gravity pipette is less than 0.0002. In the case of the falling-drop method the average difference is substantially the same, indicating that the method described here compares favorably in accuracy with the falling-drop technique.

The results obtained in the case of specimen No. 4 are of special interest. Repeated trials by the falling-drop method gave low values with a rather large variation among the individual determinations. This specimen was characterized by a cholesterol content of over 850 mg. per 100 c.c., 33 per cent of which was present in the form of the ester. Whether or not the failure to obtain satisfactory results can be ascribed to the unusually high content of these constituents was not ascertained. However, no difficulty was experienced with the specific gravity pipette.

TABLE II

COMPARISON OF RESULTS OBTAINED BY THE SPECIFIC GRAVITY PIPETTE WITH THOSE OBTAINED BY OTHER METHODS

SPECIMEN	SPECIFIC GRAVITY			PROTEIN (GRAMS PER 100 C.C.)	
	PYKNOMETER	FALLING DROP	PIPETTE	PIPETTE	KJELDAHL
1	1.0187	1.0188	1.0185	3.90	3.97
2	1.0203	1.0204	1.0204	4.57	4.61
3	1.0203	1.0203	1.0205	4.61	4.73
4	1.0207	1.0198	1.0207	4.68	4.96
5	1.0222	1.0222	1.0223	5.23	5.50
6	1.0234	1.0232	1.0233	5.58	5.68
7	1.0261	1.0260	1.0263	6.63	6.62
8	1.0286	1.0284	1.0285	7.40	7.43
9	1.0311	1.0312	1.0311	8.30	8.21
10	1.0333	1.0330	1.0336	9.18	9.01

DISCUSSION

Once the apparatus has been constructed and calibrated, the determination of serum specific gravity and total protein content becomes a matter of extreme simplicity. In making a determination it is necessary merely to fill the pipette, stretch a rubber band over the ends, invert it, and take the reading. In fact, a fair degree of accuracy can be obtained simply by inverting the pipette while it is attached to a rubber suction tube provided with a glass bead valve, thus dispensing with the use of a rubber band. For the greatest accuracy the use of the rotating holder is advised.

The pipette is cleaned and dried quickly by drawing water through it, followed by alcohol, ether, and air.

It is important to know the temperature at which a measurement is made. Ordinarily the reading of a thermometer placed near the apparatus is sufficient. In order to avoid warming the liquid, the pipette should be handled only by the capillary stems at points well removed from the bulb.

Certain other precautions should also be observed. Rotation must be carried out at such a rate that the beads will be kept in place by centrifugal force and yet not be thrown out of position as the inverted pipette is brought to rest. On account of the viscosity of serum this operation is not particularly critical and can be learned by a few trials. The most serious source of error arises from small air bubbles which adhere to the glass beads. These are readily seen in good light and when present must be shaken off. Difficulty from this source rarely occurs with serum used soon after centrifuging. It is most likely to occur with refrigerated serum, particularly if it is drawn into the pipette before coming to the temperature of the room.

Obviously, the method described here may be used to determine the specific gravity of any body fluid which is not opaque, if 1 c.c. or more is available. Various ranges may be covered by preparing glass beads of the required specific gravity. Furthermore, preliminary work has shown that the albumin and globulin fractions of serum may be determined separately by a modification of this method.

SUMMARY

1. A new specific gravity method for the determination of serum protein has been developed.
2. The method is rapid and accurate, and has the advantage of being direct reading.
3. The essential apparatus consists of a single article of glassware, the construction, calibration, and use of which are described in detail.

I am indebted to Dr. Newton Evans, of the Los Angeles County General Hospital, for his assistance in obtaining many serum specimens used in this work.

DEPARTMENT OF ABSTRACTS AND REVIEWS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

TISSUE: Modification of Mallory's Phosphotungstic Acid-Hematoxylin Stain for Formaldehyde-Fixed Tissues, Peers, J. H. Arch. Path. 32: 446, 1941.

1. Deparaffinize sections and bring down to water.
2. Mordant three hours in a saturated aqueous solution of mercuric chloride in a paraffin oven at 57° C. Rinse briefly. The mercuric chloride solution may be used repeatedly.
3. Place in compound solution of iodine for five minutes. Rinse.
4. Place in 5 per cent aqueous solution of sodium thiosulfate for five minutes. Rinse.
5. Place in 0.25 per cent potassium permanganate for five minutes. Rinse.
6. Place in 5 per cent aqueous oxalic acid for five minutes. Wash well.
7. Stain overnight in phosphotungstic acid hematoxylin.
8. Wash briefly in tap water, dehydrate in alcohol or acetone, clear in xylol, and mount in balsam.

This technique gives results almost identical with those of the original method as applied to tissue fixed in Zenker's solution. Neuroglia, fibroglia, and myoglia fibrils, blepharoplasts, nuclei, red blood cells, and fibrin are deep blue, while collagen is brownish red.

TULAREMIA, Lawless, T. K. Arch. Dermat. & Syph. 44: 147, 1941.

The following antigen is proposed:

The pus from an unopened gland is aspirated and divided into three equal portions. These separate portions are triturated with ten volumes of acetone, alcohol, and 0.4 per cent saline solutions. The mixture is allowed to digest for twenty-four hours, with frequent agitation. The supernatant fluids are pipetted off and mixed. The alcohol and acetone are allowed to evaporate, and the original volume is made up with 0.4 per cent saline solution. The solution is sterilized on a water bath at 60° C. for two hours and twenty-four hours later for one hour. Tests for sterility are performed on agar plates. Phenol, 0.25 per cent, is then added.

As a test material, 0.1 c.c. is introduced intradermally, and the reaction is read at the end of one-half hour. A large erythematous, edematous wheal with pseudopodia in some cases will result in a case of the disease. This reaction remains for twenty-four or more hours, depending on the severity of the condition. A control subject should show either no reaction or one that disappears in ten to fifteen minutes. In patients presenting non-specific reactions, the wheal disappears in from one to two hours. The earliest time at which a positive result was obtained was one day after onset of symptoms. Two weeks later a positive reaction was obtained with a tularemia agglutination test with a 1:1,280 dilution. The oldest condition was recognized five months after infection and had been diagnosed and treated as influenza, pneumonia, and empyema.

This antigen also agglutinates the red blood cells of infected persons and produces a specific histiocytic response in the local tissues.

PLASMA PROTEINS, Simple Method for Estimating, Walther, W. W. Lancet 241: 337, 1941.

Materials: Pyrex boiling tubes, 170 mm. by 28 mm., marked by a ring at 25 cm.
"Antibump" device consisting of 5 mm. of glass tubing fused to the end of a glass rod 160 mm. long.

Pure, nitrogen-free sulfuric acid.

Pure, nitrogen-free potassium persulfate saturated solution.

Nessler's solution (special for blood testing).

Nitrogen standard. Pure ammonium sulfate, 0.03776 Gm. per liter of distilled water containing 7 c.c. of pure sulfuric acid. It is convenient to prepare this by diluting 8 c.c. of a 0.472 per cent solution of the salt to 1 liter.

Analyses may be done on heparinized plasma (using the minimum of heparin) or on serum.

Method: After washing out the boiling tube with distilled water, about 0.5 c.c. of water collects in it. Using the hemoglobin pipette, wash out 20 c.c. of serum or plasma into this water. Add 0.25 c.c. of pure sulfuric acid and mix. Boil gently over by-pass flame of Bunsen burner with "antibump" rod in position. When thick white fumes rise and fill the tube, cover with a watch glass and boil for three minutes. The solution is then quite black. Remove the flame for two minutes, and then add 0.5 c.c. of saturated potassium persulfate solution. Mix with antibump rod and replace flame. Boil without watch glass until thick white fumes rise again, then replace the watch glass and boil for two minutes longer, after which the solution will be clear and colorless. Cool, dilute with distilled water to the 25 c.c. mark, holding the tube with the 25 c.c. mark at eye level and remove the antibump rod. Replace the rod and wash well in the solution. Use any convenient volume (the author uses 5 c.c. of the solution placed in an ordinary test tube), and add 2 c.c. of Nessler's solution. A similar volume of standard solution is treated in the same way. Mix by inverting twice and compare at once in the colorimeter. Equal color indicates 1,000 mg. of total nitrogen per 100 c.c. of sample. A direct reading may be obtained by fixing the unknown at 10 and moving the standard to match. The reading of standard times 100 equals milligrams of total nitrogen per 100 c.c. of sample. The reading is greatly facilitated by placing a spectrum blue color filter over the eyepiece. Unless gross nitrogen retention is suspected, a subtraction of 50 mg. to cover the nonprotein nitrogen gives the figure for protein nitrogen which, when multiplied by 6.25/1,000 gives the protein percentage. The reagents should be tested occasionally by blank estimations.

If a colorimeter is not available, a comparator or similar instrument can be used, but the reading of the yellow Nessler solution is greatly helped by using a blue light filter. The accuracy of the method depends on individual skill in color matching, but it is well within the limits necessary for clinical work.

DIPHTHERIA, Present Status of the Immediate Tellurite Test for, Bierman, H. R., and Maxwell, R. W. J. A. M. A. 117: 1255, 1941.

The potassium tellurite procedure for the differential diagnosis of diphtheria, as suggested by Manzullo, was applied to 117 patients exhibiting membranes of the throat.

The test was frequently positive on nondiphtheritic membranes but was falsely negative only twice.

A negative tellurite reaction, if it contradicts the clinical impression, is not sufficiently reliable to justify one in withholding antitoxin therapy.

It is felt that the technical difficulties of applying the test at present, and the frequency with which both false positive and false negative reactions are obtained, make it unsatisfactory as a routine guide for the therapy of diphtheria. Refinements in technique might admittedly enhance its usefulness.

SYNOVIAL FLUID and Synovial Membrane Abnormalities Resulting From Varying Grades of Systemic Infection and Edema, Coggeshall, H. C., Bennett, G. A., Warren, C. F., and Bauer, W. Am. J. Med. Sc. 202: 486, 1941.

From a study of 156 post-mortem synovial fluids and 49 synovial tissue specimens obtained from persons dying with varying degrees of infection and edema, the following conclusions can be drawn:

1. The amount of synovial fluid in the knee joints of persons with peripheral edema is usually increased.

2. The synovial fluid obtained from the joints of edematous patients contains fewer nucleated cells than does normal fluid and its total solids, viscosity, protein, and mucin contents are reduced.

3. Total nucleated cell counts and the absolute number of neutrophils in synovial fluid specimens obtained from patients dying with varying degrees of infection are frequently increased. The most marked cytologic abnormalities are observed in patients dying with severe infections and associated septicemias.

4. An increase in the absolute number of neutrophils is a more reliable indication of the existence of synovial tissue inflammation than are increased total nucleated cell counts or random biopsies.

5. The synovial fluid abnormalities resulting from synovial tissue infections vary with the severity of the synovial lesion and its proximity to the joint space.

6. The results of the present study suggest that the joint aches and pains occurring in various infectious diseases may be the result of synovial tissue inflammatory changes caused by blood-borne infections. The majority of such inflammatory lesions are presumably mild in nature and, therefore, resolve readily. The marked synovial tissue reactions observed in patients dying with septicemia are of the type observed in early cases of specific infectious or septic arthritis.

TRANSFUSIONS, Infusions of Blood and Other Fluids Via the Bone Marrow, Tocantins, L. M., O'Neill, J. F., and Jones, H. W. J. A. M. A. 117: 1229, 1941.

Citrated blood and physiologic solution of sodium chloride have been infused through the marrow of a tibia or a femur of 9 infants in whose treatment intravenous infusions were urgent but impossible. In 2 with congenital anemia and erythroblastosis, it was not possible to infuse any blood by this method. No local or constitutional reactions, immediate or delayed, have been disclosed by clinical and roentgen-ray examinations after these infusions. When clearly indicated, the intramedullary route for parenteral therapy is feasible and useful.

BLOOD IODINE: Naturally Occurring Iodine Fractions and Their Chemical Behavior, Bassett, A. M., Coons, A. H., and Salter, W. T. Am. J. Med. Sc. 202: 516, 1941.

The protein-bound iodine in the blood plasma of man and of animals was found to reside chiefly in the traditional albumin fraction. This iodine was subject to fluctuations dependent upon thyroid activity. Such fluctuations, in absolute terms, were due chiefly to a thyroxine-like moiety thereof. The moiety resembling diiodotyrosine might increase proportionately, but it contributed relatively little to the absolute change from the normal level. Accordingly, total protein-bound iodine fluctuated largely with thyroxine-like iodine. In myxedema the thyroxine-like fraction practically disappeared.

Despite variations in this protein-bound iodine, the ionized iodine (inorganic) appeared to be rather low and approximately constant under the conditions of this study, regardless of the state of thyroid activity. Nevertheless, it was found to increase markedly when extraordinary, though perhaps very small, amounts of iodine entered the organism. Simultaneously a false increase in the protein-bound iodine occurred which could be reproduced by the addition of iodide to plasma in vitro.

The results indicate that the protein-bound thyroxine-like moiety of the plasma iodine is a good objective index of circulating thyroid hormone. They suggest, also, that plasma protein-bound iodine might be used clinically to confirm physiologic thyroid status.

BLOOD IODINE: Its Relation to Thyroid Function in 100 Clinical Cases, Salter, W. T., Bassett, A. M., and Sappington, T. S.

A series of 100 cases of suspected thyroid disturbance and 10 control patients have been analyzed from the standpoint of final clinical diagnosis, basal metabolic rate, and plasma protein-bound iodine. When the first two of these criteria are in agreement, there is a close correlation between the plasma iodine and the basal metabolic rate. Such cases amount to 71 per cent of the entire group studied. Of the remaining 20 per cent, the basal metabolic rate often did not clearly reflect the clinical status and the plasma protein-bound

iodine proved much more reliable. This was particularly true in the group of "Graves' without hyperthyroidism" in which the basal metabolic rate ranged from -20 to +40 per cent, but the plasma protein-bound iodine was normal. These data, therefore, constitute additional evidence for the possible dissociation of physiologic hyperthyroidism and clinical Graves' disease. In hypothyroidism plasma protein-bound iodine appears to be a highly reliable criterion for confirming lack of thyroid hormone, even when full-blown myxedema is absent.

It has been emphasized that the simplified chemical procedures employed are partly empirical. Their use has been justified by their consistency with clinical data, but due care should be exercised in comparing the data with the results obtained by other methods.

BLOOD: The Use of Rabbit Thrombin as a Local Hemostatic, Lozner, E. L., MacDonald, H., Finland, M., and Taylor, F. H. L. Am. J. Med. Sc. 202: 593, 1941.

Observations are reported indicating that rabbit thrombin is of distinct value in the control of hemorrhage from small wounds induced by a standard trauma in normal persons and in 9 patients with and in 2 patients without hemorrhagic diatheses bleeding spontaneously from small wounds.

The material apparently accomplishes its results by the instantaneous precipitation of fibrin.

No toxic manifestations were observed following the application of rabbit thrombin to the small wounds.

It would appear desirable that these observations concerning the use of rabbit thrombin as a local hemostatic be extended.

BLOOD: The Thrombic Activity of a Globulin Fraction Derived From Rabbit Plasma, Taylor, F. H. L., Lozner, E. L., and Adams, M. A. Am. J. Med. Sc. 202: 585, 1941.

The observation of Parfentjev that rabbit plasma contains a substance or physiologic activity capable of converting fibrinogen to fibrin is confirmed.

Parfentjev's material is apparently a pseudoglobulin which possesses true thrombic activity.

It may be differentiated from thromboplastin by its manner of preparation and its independence of calcium-ion concentration in its action on fibrinogen.

Methods of preparing the material in a stable powdered form are presented.

BLOOD CLOTTING: A Globulin Fraction in Rabbit's Plasma Possessing a Strong Clotting Property, Parfentjev, I. A. Am. J. Med. Sc. 202: 578, 1941.

A description is given of a globulin fraction, isolated from rabbit plasma, which possesses the property of clotting plasma.

It has been found that the "toxicity" of this fraction on intravenous injection is due to intravascular clotting.

Clotting globulin could be separated from that fraction of rabbit plasma which contains the major portion of the immune bodies.

CLINICAL AND EXPERIMENTAL

AGGLUTINATION REACTIONS IN RHEUMATOID ARTHRITIS*

JOHN L. FERRY, M.D., AND LUKE W. HUNT, M.D.
CHICAGO, ILL.

BACTERIOLOGIC investigations in rheumatoid arthritis have been undertaken frequently since Billings, Rosenow, and others, advanced the theory of focal infection as a possible etiologic agent in this disease.

A considerable stimulus to this type of investigation was given by the work of Cecil, Nicholls, and Stainsby,¹ who reported the isolation of a streptococcus from the blood stream of 61.5 per cent of 78 patients with rheumatoid arthritis—83.3 per cent of the positive cultures yielded organisms culturally and biologically identical—the “typical strain”—an attenuated hemolytic streptococcus.

Although others were unable to confirm this finding of positive blood cultures in rheumatoid arthritis, attention was turned to the fact that these “typical strains” of hemolytic streptococci were found by Nicholls and Stainsby² to be agglutinated in high dilutions by the sera of a large percentage of cases of this disease; 103 cases in 110 (93 per cent) had agglutinations of 1:640 or higher. Among 218 controls the majority were negative, and when agglutination was present it usually was in titer of less than 1:160. Hemolytic streptococci from other sources gave comparable reactions in lower titer. *Streptococcus viridans* gave weakly positive reactions. Sera from patients with other types of arthritis, febrile and nonfebrile diseases, and normal people, in most instances failed to agglutinate the organisms in significant titer.

*From the Department of Medicine, University of Chicago, Chicago.
Received for publication, February 1, 1941.

This work was repeated by Dawson, Olmstead, and Boots³⁻⁵ who found no correlations between the source of the hemolytic streptococci and the agglutination titers obtained. Absorption tests failed to show specificity of the agglutination reaction for the strains of hemolytic streptococci examined. They found that in 206 patients with rheumatoid arthritis, 113 (54.8 per cent) had agglutinations of 1:160 or higher. A total of 256 control cases were negative or the agglutinations were of lower titer. They felt that there was a definite relation between the agglutination reaction and the age of the patient, and the duration of the disease. Examination of 41 other strains of gram-positive cocci failed to show comparable titers of agglutinations except tests using rough strains of pneumococci.

Blair and Hallman⁶ examined the sera of 62 patients with rheumatoid arthritis and found that 82 per cent of them agglutinated "typical strain" AB66 in dilution of 1:160 or higher. Strains of hemolytic streptococci from other sources were agglutinated less frequently or in lower titers. A total of 32.9 per cent of 94 controls were positive in dilution of 1:160 or higher. They were unable to demonstrate any correlations between the agglutination titer and the age of the patient, the duration of the disease, the number of joints involved, or the sedimentation rate.

Gray and Gowen⁷ found agglutination in some degree in 52 of 60 cases (86.6 per cent) against one of the "typical strains," AB13-45 (75 per cent) were in a dilution 1:160 or higher. The majority of cases of long standing showed agglutination in low titer, if at all.

Dawson and Wetherby⁸ reported a strain of hemolytic streptococci isolated from a patient with chronic arthritis, agglutinated by 98.1 per cent of 60 persons with chronic arthritis and 28 per cent of controls in a titer of 1:400 or higher.

Cox and Hill⁹ found that 197 sera from patients with rheumatoid arthritis agglutinated "typical strain" AB13 in approximately 70 per cent of cases in a titer of 1:320 or higher. Other organisms, including another strain of *Streptococcus hemolyticus*, *Streptococcus viridans*, *Streptococcus anhemolyticus*, *Staphylococcus aureus*, and *B. coli* were agglutinated in dilutions of 1:320 or higher in from 8 per cent to 49 per cent of cases.

McEwen, Bunim, and Alexander,¹⁰ using a scarlet fever strain NY5, report positive agglutinations in 86 per cent of 36 patients with atrophic arthritis, 56 per cent in a dilution of 1:160 or higher. None of 35 normals had positive agglutinations.

Goldie and Griffiths¹¹ found that 80 per cent of 31 patients with rheumatic fever and chorea, 89 per cent of 28 patients with chronic infectious arthritis, 71 per cent of 17 patients with "streptococcal diseases," and 10 per cent of controls agglutinated stock strains of hemolytic streptococci in a dilution of 1:160 or higher.

Hartung, Davis, Steinbrocker, and Straub¹² report "typical strain" AB13 agglutinated by 36 per cent of 50 patients with rheumatoid arthritis 1:160 or higher. Two strains of hemolytic streptococci from other sources were agglutinated in 30 per cent and 24 per cent by the same sera. Ten per cent of normals were positive.

Tillett and Abernathy¹³ found that in a number of bacterial infections other than streptococcal, the sera of the patients are capable of agglutinating certain strains of hemolytic streptococci. The reaction is demonstrable soon after the onset, persists during the active stage, and disappears after recovery. This agglutinability is striking when live organisms or organisms killed by formalin are used, but disappears if cultures are heated to the thermal death point.

Keefer, Myers, and Oppel,¹⁴ therefore, performed a large group of agglutination tests using heat-killed organisms. The sera of 12 patients in 22 (55 per cent) with rheumatoid arthritis gave positive reactions; 9 patients (41 per cent) had agglutinations in a titer of 1:160 or higher. Only one serum agglutinated in a titer above 1:640. Positive reactions were obtained in 26.2 per cent of patients with rheumatic fever (42), 9.7 per cent of rheumatic heart disease,³¹ 14.3 per cent of degenerative arthritis,²⁸ 23.5 per cent of erysipelas.¹⁷ Sera from patients with other forms of arthritis, and a number of infectious and noninfectious diseases failed to agglutinate heat-killed streptococci. The reaction in patients with rheumatoid arthritis persisted for one to several months. In some cases it was maintained by intravenous vaccine.

Wainwright¹⁵ performed a series of agglutinations with the sera of 51 patients with rheumatoid arthritis using both heat-killed and living hemolytic streptococci. He found the heat-killed organisms were agglutinated in slightly lower titers, but otherwise the curves were similar.

Wainwright,¹⁶ in another investigation, found that agglutination of hemolytic streptococci by sera of patients with rheumatoid arthritis was not confined to organisms of group A (Lancefield), or to streptococci from human sources. Absorption with a representative strain of one group removed the agglutinins not only for that strain but for others of the same group—bearing out group specificity of the reaction rather than strain specificity.

McEwen, Chasis, and Alexander¹⁷ did similar agglutination tests using strains of hemolytic streptococci of Lancefield's groups A, B, C, D, E, F, and G. The strongest agglutinations occurred in group A, but definite reactions were also obtained in the other groups. Crude C extracts of all groups were prepared, and when these were tested with the sera of patients with rheumatoid arthritis, occasional crossing was found with the extracts of all groups, and frequently with those of groups A, B, and G.

Chasis and McEwen¹⁸ pursued this line of investigation further and found that cross reactions occurred with crude C extracts of hemolytic streptococci of the various groups, when used in precipitin tests with immune human sera and with immune rabbit sera, and the sera of patients with rheumatoid arthritis, rheumatic fever, and convalescent scarlet fever. This reaction was thought to be due to the presence of antibodies in the sera against a nongroup specific ration present in the bacteria and in the crude C extracts, this substance being of nonprotein nature.

Dawson and Olmstead¹⁹ examined the sera of 76 patients with rheumatoid arthritis for agglutinins against organisms in Lancefield groups A, B, C, D, E, F, and G. Using group A they found the percentage of positive reactions to be approximately the same as they had reported previously,⁴ or about 55 per cent.

However, there were only three instances of definite positive reactions (1:160 or above) with organisms other than group A, and two of these were strongly positive for group A also. Control sera agglutinated groups B to G in as high dilution as did the sera of patients with rheumatoid arthritis. Control sera which agglutinated group A organisms in titers comparable with that of rheumatoid arthritis were found only in proved severe hemolytic streptococci infections.

Dawson, Olmstead, and Jost²⁰ compared the agglutinins and precipitins against hemolytic streptococci in 71 patients with rheumatoid arthritis and in 79 controls. They demonstrated a close approximation but not an absolute agreement between the capacity of rheumatoid arthritis sera to agglutinate strains of hemolytic streptococci and to precipitate various group-specific fractions of this organism. Bunim and McEwen²¹ found no correlations between the anti-streptolysin titer and the hemolytic agglutination titer. Eighty-five per cent of 205 sera from 75 patients with atrophic arthritis had antistreptolysin titers within normal limits regardless of the stage of the disease or severity of clinical symptoms.

Short, Dienes, and Bauer²² compared the results obtained in 49 patients with typical rheumatoid arthritis, using the sedimentation rate, Arneth-Schilling counts, the Vernes resorcinol test, and agglutination tests with hemolytic streptococci. A total of 92.2 per cent of the patients showed elevated sedimentation rates; 87 per cent of the Schilling counts were positive (over 8 per cent young cells), 58.3 per cent of the Vernes tests were positive; 53.1 per cent of agglutinations showed a titer above 1:160 for at least one of the four strains employed.

The evidence which has accumulated from these investigations shows that in rheumatoid arthritis there are, in a fairly large percentage of cases, positive agglutinations for hemolytic streptococci, regardless of the source of the organisms. This reaction comes on during the course of the disease, persists a variable length of time, varying in strength, and usually is low in titer or absent when the disease reaches a quiescent stage. Heat-killed streptococci are agglutinated similarly but in lower titer than with live organisms. Agglutinations are strongest with organisms of Lancefield's group A, but are present in other groups, and definite cross reactions frequently occur. There seems to be a close relationship between the agglutinins and precipitins for hemolytic streptococci, but none between agglutinins and antistreptolysins in rheumatoid arthritis. Elevated sedimentation rates and positive Schilling counts are considerably more constantly present than the resorcinol test and the agglutination reaction.

As indicated in the preceding reports, there is a wide variation in the results of the agglutination tests in different hands, and marked differences of opinion as to their significance.

Consequently, we performed a series of agglutination tests on patients with typical rheumatoid arthritis, with osteo-arthritis, with a number of related conditions, and on normal controls using a number of strains of hemolytic streptococci from various sources, and with two strains of *Streptococcus viridans*. This investigation was undertaken in an attempt to evaluate the agglutination reaction in relation to the patients seen in out-patient arthritis clinic.

METHOD

The medium used for cultures was dextrose broth. Flasks of this media were inoculated with a diffuse fairly dense culture and incubated at 37° C. for fifteen to twenty-four hours.

Serum dilutions were made with 0.8 per cent sodium chloride solution in proportions of 1:10, 1:20, 1:40, 1:80, 1:160, 1:320, 1:640, 1:1,280, 1:2,560, and 1:5,120. To these dilutions 0.5 c.c. of culture was added, making the final dilutions 1:20, 1:40, 1:80, 1:160, 1:320; 1:640, 1:1,280, 1:2,560, and 1:5,120. A control consisting of 0.5 c.c. of culture and 0.5 c.c. of broth was included in all the tests.

TABLE I
AGGLUTINATION TITER OF SERA OF PATIENTS WITH ARTHRITIS WITH HEMOLYTIC STREPTOCOCCI

TYPE OF CASE	TITER OF AGGLUTINATION											PER-CENT-AGE POSITIVE	PER-CENT-AGE NEGATIVE
	NEGATIVE	1:20	1:40	1:80	1:160	1:320	1:640	1:1,280	1:2,560	1:5,120	TOTAL CASES		
Typical rheumatoid arthritis	3	1	3	8	5	5	4	4	1	2	36	58	42
Typical osteoarthritis	8	1	4	5	4	2	0	0	1	0	25	28	72
Related diseases	5	0	1	1	1	0	1	0	1	0	10	30	70
Controls	19	1	8	3	0	2	1	1	1	0	36	13.9	86.1

Agglutination tests were placed in a water bath at 56° C. for two hours and then overnight in the icebox. The tests were read at the end of two hours and after overnight refrigeration.

Readings were made after gently tapping the tubes until the bacteria had risen from the bottom. The reactions were recorded by the following scale:

- ++++ Disk or firm clump—broth clear.
- +++ Loose clumps, readily broken—broth clear.
- ++ Small clumps—broth clear.
- + Small but distinct clumps—broth cloudy.
- No clumps visible.

The highest dilution in which distinct and small clumps were observed was considered the end point or titer. The hemolytic activity of the strains employed was tested on blood agar.

Six strains of hemolytic streptococci were used in the agglutination tests. They were obtained from the following sources:

Strain I. From the throat of patient with scarlet fever.

Strain II. From patient with erysipelas.

Strain III. From throat of patient with rheumatoid arthritis and nephritis. This strain produces typical rheumatoid arthritis in rabbits.

Strain IV. From throat of patient with nephritis.

Strain V. From throat of patient with nephritis.

Strain VI. From dog tonsil.

Agglutination test was performed with at least three of these strains with the serum of each patient.

A smaller number of agglutination tests were performed with two strains of green streptococci obtained from the following sources:

Strain 1. From extracted tooth of patient with rheumatoid arthritis.

Strain 2. Blood culture from patient with subacute bacterial endocarditis.

The results are summarized in Table I. Agglutination titers of 1:160 or higher were obtained in 21, or 58 per cent, of 36 patients with typical rheumatoid arthritis. In 25 patients with typical osteo-arthritis, agglutination titers of 160 or higher were obtained in 7, or 28 per cent; in 10 patients with related diseases—rheumatic fever, fibrositis, and gonorrheal arthritis—positive agglutination reactions were obtained in 3, or 30 per cent. In the control group of 36 patients positive agglutination reactions were obtained in 5, or 13.9 per cent.

TABLE II

RELATIONSHIP BETWEEN DURATION OF DISEASE AND AGGLUTINATION REACTION IN RHEUMATOID ARTHRITIS

DURATION OF DISEASE	NEGATIVE	1:20	1:40	1:80	1:160	1:320	1:640	1:1280	1:2,560	1:5120	TOTAL CASES
Six months or less				2	2	1	1				6
One year		1		1	1					1	4
One to five years			3	5	2	3		2			15
Over five years	4			1	2	1	2			1	11
Total											36

DURATION

One Year or Less

Positive—6 cases, or 60 per cent
1:160 or higher

Negative—4 cases, or 40 per cent
under 1:160

Over One Year

Positive—13 cases, or 50 per cent

Negative—13 cases, or 50 per cent

TABLE III

AGGLUTINATION TITER OF SERA OF PATIENTS WITH ARTHRITIS WITH *STREPTOCOCCUS VIRIDANS*

TYPE OF CASE	TITER OF AGGLUTINATION										PERCENTAGE POSITIVE	
	NEGATIVE	1:20	1:40	1:80	1:160	1:320	1:640	1:1,280	1:2,560	1:5,120		TOTAL CASES
Typical rheumatoid arthritis	9		4	3	3		1				20	20
Typical osteo-arthritis	4		3	1	1	1					10	20
Related diseases												
Controls	7	1	1	1		1					11	9

The relation of the duration of the disease to the agglutination titer is shown in Table II. In this series there seemed to be no relationship between the two conditions. The results obtained with the two strains of *Streptococcus viridans* are summarized in Table III. Agglutination titers of 1:160 or higher were obtained in 4, or 20 per cent, of 20 patients with rheumatoid arthritis, with 2, or 20 per cent, of 10 patients with osteo-arthritis and in 1, or 9 per cent, of 11 controls.

SUMMARY AND CONCLUSIONS

Previous experimental work on this subject is reviewed briefly. The agglutination titer of sera of 36 patients with rheumatoid arthritis, of 25 patients with osteo-arthritis, of 10 patients with related conditions, of 36 normal controls with strains of hemolytic streptococci obtained from various sources was determined. Agglutination titers of 1:160 or higher were obtained in 58 per cent of the patients with rheumatoid arthritis; in 28 per cent of those with osteo-arthritis, in 30 per cent of those with related conditions and in 13.9 per cent of the controls.

In this series there seemed to be no relationship between the duration of the disease and the agglutination titer.

Agglutination titers of 1:160 or higher were obtained with two strains of *Streptococcus viridans* in 20 per cent of 20 patients with rheumatoid arthritis, in 20 per cent of 10 patients with osteo-arthritis and in 9 per cent of 11 controls.

Although the percentage of positive agglutination reactions is considerably higher in patients with rheumatoid arthritis than in patients with osteo-arthritis, related conditions and controls, the reaction is of little value as a diagnostic measure, because patients with typical rheumatoid arthritis may have negative tests, and controls give positive reactions often enough to be confusing. The test is time-consuming, tedious, and difficult to perform accurately. No positive information is derived from agglutination reactions as to the etiology of the disease.

In the present state of immunological knowledge the significance of the agglutination reaction in rheumatoid arthritis is largely a matter of conjecture and is nothing more than suggestive. Whether infection by the hemolytic streptococcus plays a role of primary or secondary importance in the production of the disease, will require more evidence than that obtained from agglutination reactions.

INTRAMUSCULAR ADMINISTRATION OF SODIUM SULFAPYRIDINE TO CHILDREN*

GILBERT M. JORGENSEN, M.D., R. WENDELL COFFELT, M.D., AND
JULES C. WELCH, M.D., LOS ANGELES, CALIF.

THOUGH a report¹ on the intramuscular administration of sodium sulfapyridine to patients appeared as early as July, 1939, this route has not been employed extensively. A recent favorable report² in this JOURNAL on the intramuscular route for parenteral administration of sodium sulfapyridine prompted the publication of our clinical experience and experimental work with the intramuscular administration of this drug.

Because such injections usually must be given by a physician, it seemed desirable to give them as infrequently as practicable. Our experience leads us to believe that in most infants and young children a satisfactory blood sulfapyridine level can be maintained by an intramuscular injection of sodium sulfapyridine no oftener than every twelve hours.

One hundred and ten intramuscular injections of a 30 per cent aqueous solution of sodium sulfapyridine monohydrate were given to 71 patients. The

*From the Children's Hospital of Los Angeles and the Department of Pediatrics, University of Southern California Medical School.

The sodium sulfapyridine was supplied by the Calco Chemical Company.

Received for publication, January 29, 1941.

dosages, calculated as sodium sulfapyridine monohydrate, were approximately as follows:

16 injections of 0.05 Gm. per kilogram of body weight
75 injections of 0.1 Gm. per kilogram of body weight
18 injections of 0.2 Gm. per kilogram of body weight
1 injection of 0.3 Gm. per kilogram of body weight

When the total volume to be given amounted to more than 10 c.c., the dose was divided and given into two sites. Most of the injections were given as an initial dose to patients who were critically ill with pneumonia, and usually oral administration of sulfapyridine was begun within a few hours. The injections were given deep into the gluteal or quadriceps muscles. The number of injections in each patient was as follows:

53 patients received 1 injection
9 patients received 2 injections
4 patients received 3 injections
1 patient received 4 injections
2 patients received 5 injections
1 patient received 6 injections
1 patient received 7 injections

For 21 patients oral administration of sulfapyridine was withheld for one to twenty-four hours in order to determine the course of the blood sulfapyridine level after a single intramuscular dose (Table I).

TABLE I

BLOOD SULFAPYRIDINE LEVELS FOLLOWING A SINGLE INTRAMUSCULAR DOSE OF A 30 PER CENT AQUEOUS SOLUTION OF SODIUM SULFAPYRIDINE MONOHYDRATE

The dosage is expressed as grams of sodium sulfapyridine monohydrate per kilogram of body weight.

CASE	WEIGHT KG.	DOSE GM./KG.	FREE SULFAPYRIDINE LEVELS IN MG./100 C.C. OF BLOOD				
			HOURS AFTER INJECTION				
			1	4	6	12	24
1	18	0.06	3			3	
2	22	0.06	2			3	
3	6.7	0.1	8				
4	6.8	0.1	3			4	
5	7.2	0.1	4		8		
6	8.5	0.1	5				
7	11	0.1	3	5			
8	12	0.1	5		8		
9	15	0.1				7	
10	16	0.1	7				
11	16	0.1	5		7	5	0.8
12	18	0.1	4		8	5	
13	19	0.1	3		8	5	0.9
14	22	0.1	4				
15	25	0.1	5				
16	9.4	0.2	6		11	8	3
17	15	0.2				12	
18	18	0.2	6		10	6	4
19	19	0.2	9	13	12	9	2
20	22	0.2	9	12	11		5
21	13	0.3	8			15	

The local reaction in most cases was surprisingly slight. Considerable pain was a complaint during the injections, but it subsided within a few minutes. Slight tenderness and, in a few cases, some induration at the site of injection persisted for a day or two. Due to a misunderstanding one injection was given subcutaneously, resulting in a slough about 3 cm. in diameter. The patient had a staphylococcus bacteriemia, which resulted in death a few days later. In one fat infant a deep slough about 3 cm. in diameter followed an injection of 0.2 Gm. per kilogram of body weight (6 c.c.) into the gluteal region. Since the depth of the subcutaneous fat in this infant was nearly as great as the length of the needle used, it is possible that the solution was not given into the muscle. In another infant the skin at the site of the needle puncture became necrotic for an area of about 1 cm. in diameter; this healed without ulceration.

If one uses the intramuscular route sloughs from accidental subcutaneous administration must be expected occasionally, but with proper precautions they should rarely occur. It is important to remember that on a well-nourished infant the subcutaneous fat in the gluteal region may be more than an inch thick.

From two patients who died one day after injection, specimens of muscle were obtained from the injected sites. The only gross changes noted were hemorrhage into the muscle in both cases and the deposition of a few small crystals in one. Microscopically there were hemorrhage, infiltration with polymorphonuclear neutrophiles, and swelling and loss of cross striation of the muscle fibers.

In order to obtain further information regarding the severity of the damage to the muscle, each of ten rabbits was injected with 5 c.c. of the solution into the extensor muscles of the thigh. Although this volume amounted to a very large dosage for the rabbits, it was chosen because it represented about the average volume given to patients. The rabbits were autopsied at intervals of one to thirty-three days after the injections. The reaction in the muscle in all the rabbits was limited in the main to an area about 3 cm. in diameter. In some rabbits there were changes along the fascial planes for a slightly greater distance.

Rabbits autopsied on the first, second, third, and fifth days showed similar changes, except that crystals were found in the muscle only in the first rabbit. The crystals extended throughout an area about 1 cm. in diameter. Hemorrhage was the only other gross change noted. Microscopically, there were hemorrhage, edema, infiltration with polymorphonuclear neutrophiles, and round cells, and loss of the staining properties of the muscle fibers.

The gross change in the muscles of the rabbits autopsied on the ninth, thirteenth, eighteenth, and twenty-third days consisted only of a brownish discoloration. Microscopically, there were degenerative changes in the muscle fibers; infiltration with polymorphonuclear neutrophiles, round cells, and giant cells; and some increase in fibrous tissue.

The muscles from the two rabbits autopsied on the thirty-third day showed no gross changes, but microscopically, there was an infiltration with giant cells and an increase in fibrous tissue.

CONCLUSION

A 30 per cent aqueous solution of sodium sulfapyridine monohydrate may be given intramuscularly to children when other routes of administration are not practicable. Following a dose of 0.1 Gm. per kilogram of body weight, a blood sulfapyridine level between 5 and 10 mg. per cent may be expected throughout most of the first twelve hours. The danger of a slough should not be great if proper precautions are taken to insure injection into the muscle. Although crystals (presumably sulfapyridine) may precipitate at the site of the injection, blood level studies on patients suggest that most of the solution is absorbed during the first twelve hours, and autopsy studies on rabbits demonstrate that crystals do not remain long at the site of the injection. The intramuscular injection of sodium sulfapyridine results in prolonged and perhaps permanent damage to the muscle, but the area involved is not large. The pathologic studies suggest that it may be undesirable to give more than one injection into any one site.

4614 SUNSET BOULEVARD

I. DAILY VARIATIONS IN THE TOXICITY OF NEOARSPHENAMINE
IN RABBITS*

A. J. NEDZEL, M.D., CHICAGO, ILL.

IN THE last decade Petersen¹ has shown that the "normal fluctuations" in human blood chemical levels are definitely interrelated and correlated with the weather. He also called attention to the possibility of variations in response of human beings to drugs in connection with this constantly changing physiologic state of the body and on his suggestion experimental investigations with morphine sulfate on mice were performed (Nedzel,^{2,4} and Sargent and Nedzel³). It was found that the meteorologic conditions definitely varied the toxicity of morphine sulfate. Previously Macht⁵ found a very definite influence of barometric pressure and other meteorologic conditions on the potency of digitalis for cats, and pointed out that the difference in the toxicity is due to changes in the physiologic functions of the cats, more particularly to changes produced in the respiration and circulation by the fall in barometric pressure. He concluded that fluctuations in barometric pressure and other changes in atmospheric conditions play an important role in the action of various drugs.

*From the Department of Pathology, University of Illinois, College of Medicine, Chicago. This study was made possible through a grant from the Division of Venereal Diseases of the United States Public Health Service.

Received for publication, February 6, 1941.

Here we present the observations on rabbits, which were administered neoarsphenamine. The animals used were of the same breeds, approximately of the same age. The females were all virgins, and in each daily group the same number of male and female animals was used. All animals were kept in an air-conditioned room (controlled temperature) under the same care. The diet consisted of Vitality Rabbit Ration in pellets, lettuce, and carrots. Water was supplied freely.

The experiments were performed in groups. Each day the same number of animals was injected with the same dose of neoarsphenamine per weight. The neoarsphenamine used in all these experiments was of the same lot, dissolved under similar conditions. The solution of the neoarsphenamine was never older than six minutes from the time the ampoule was opened, and was given intravenously in the ear vein. The injections were given at the same time in the morning.

The dose selected was established on the basis of an average death rate of approximately half of the number of the animals injected and was found to be 0.42 Gm. of neoarsphenamine per kilogram weight of the rabbit, as best to serve our purpose.

Winter Group.—One hundred and twenty rabbits were used in the first series, 10 rabbits being injected daily for twelve consecutive days, beginning February 17. The second series of experiments, which was started September 19, contained 150 rabbits, and the procedure was the same, namely, every consecutive day for fifteen days, 10 rabbits were receiving the same dose of neoarsphenamine as in the first group. The date of injections and the date of death, as well as the maximal and minimal daily temperature and barometric pressure for these days, are presented on Chart 1.

In the upper part of the chart are recorded the days on which the rabbits were given the neoarsphenamine intravenously, and are designated by a black dot. Each cross represents the death of one animal and is plotted on the day when this death occurred. The black lines, starting from the black dot, are extended to the right, and the crosses on these lines represent the death of a single animal on a certain day and indicate the group to which the animal belonged. Below this, the wide black field with white line in the center indicates the official temperature. The upper margin gives daily maximum temperature; the lower, the minimum temperature; the middle white line presents the mean temperature.

The lower curve indicates the official barometric pressure. Vertical lines relate days when many animals died with the corresponding temperature and barometric pressure. These lines are numbered to facilitate the discussion of events happening on the designated dates.

Arrow 1 connects the elevated peak of the barograph, low temperature, and points to the death of 4 of 10 injected rabbits. This is a day when cold air masses were passing and primarily a pressor phase existed in the animals. Line 2 shows death of 2 rabbits on the day of the injection of neoarsphenamine. At this time the meteorologic condition has been reversed in comparison with the previous day, the barometric pressure was low, and the temperature had reached a crest. Line 3 points to another 2 deaths on the same day of administration of drug; on this day the meteorologic conditions were quite different

from those of the previous day, namely, the temperature had fallen and the barometric pressure had increased rapidly. On line 4 four deaths occurred in three groups of animals previously injected. The lowest temperature and the highest barometric pressure for the period existed at this time.

Chart 1.—Mortality protocol of rabbits injected with neoarsphenamine. Spring and autumn groups. Meteorogram below. Upturned arrows indicate days of increased mortality.

Line 5 points to 8 deaths that occurred in five groups of the previously injected animals. One death occurred in the animal injected on this day; at this time the crest of the polar air mass had just passed, and barometric pressure was falling. On line 6 there were 7 deaths in five groups, one of the deaths occurring on the day of injection. The temperature was slowly rising, but the barometric pressure reached its peak, sharply rising from the previous day. Line 7 points to 7 deaths in five groups. There was a sudden fall in temperature and a sharp rise in barometric pressure. From this day on there were no more daily injections. On March 8 there were 5 deaths in four groups.

Autumn Group.—In the autumn group the death rate was lower and, as can be seen in Chart 1, the temperature was on the whole much higher and the barometric pressure varied less. Yet during this period there were certain days on which the deaths varied in comparison with the others.

Line 9 shows 9 deaths in four daily groups; a polar front passed at this time, the temperature began to fall and the barometric pressure increased. On

the next day (line 10) 6 deaths occurred in four groups. A temperature minimum was reached and the barometric pressure crest occurred. Line 11 points to 8 deaths which occurred in four groups, one death occurring on the day of injection. Though the barometric pressure on this day declined slowly, the difference between the maximum and minimum temperatures was very great, indicating the disturbed atmospheric conditions at this time. Line 12 shows only 3 deaths occurred in three daily groups, but one death occurred on the day of injection. The temperature was increasing and the barometric pressure was still increasing. On line 13 there are shown 4 deaths in three groups, and a slowly rising mean temperature; barometric pressure reached its highest peak. Line 14 shows 4 deaths in three groups and a large difference between maximum and minimum temperatures, and the lowest barometric pressure in six days. No injections were made on this day.

The following conclusions may be drawn:

1. In late winter the neoarsphenamine is more toxic for rabbits in comparison with the same dose given under similar conditions in the autumn.
2. Toxic effects of neoarsphenamine are more marked on the days when the temperature is low and the barometric pressure is high (polar air mass).
3. Neoarsphenamine is also more toxic when the temperature is unusually high and the barometric pressure falls abruptly.
4. It is also somewhat more toxic when the difference between the maximum and minimum temperatures is great.
5. Presumably atmospheric interfaces are associated with greater susceptibility on the part of the animals. The aforesaid is true for deaths occurring immediately after the injection of neoarsphenamine as well as for delayed deaths.

II. DAILY VARIATIONS IN THE TOXICITY OF NEOARSPHENAMINE IN WHITE RATS*

A. J. NEDZEL, M.D., CHICAGO, ILL.

IT HAS been shown that the toxicity of neoarsphenamine varies considerably by days in rabbits.¹ Herein are presented observations on white rats. The animals were of the same breeds, approximately of the same age. The females were virgins, and in each daily group the same number of male and female animals were used. The animals were kept in an air-conditioned room (controlled temperature) under the same care. The diet consisted of dog food cubes (given daily), lettuce—three times a week, and raw meat once a week. Water was given freely.

The experiments were performed in groups. Each day the same number of animals was injected with the same dose of neoarsphenamine, which was established on the basis of an average death rate of approximately half the number of the animals injected. The dose used was 0.225 Gm. per kilogram of weight and the injection was made at the tail. The neoarsphenamine used in all these experiments was of the same lot, dissolved under similar conditions. The solution of the neoarsphenamine was never older than six minutes from the time the ampoule was opened. The injections were administered at the same time in the morning.

The experiments on the white rats were performed in two series, the first one from May to June, and the second one from September to October, 1939. One hundred animals were used in the first series, 10 rats being injected daily for ten consecutive days, beginning May 24. The second series of experiments contained 140 animals, 10 animals per day, and began on September 19. The date of injections and the date of death, as well as the maximal and minimal daily temperature and barometric pressure for these days, are presented in Chart 1.

In the upper part of the chart are recorded the days, designated by black dots, on which the rats were given the neoarsphenamine at the tail. Each cross represents a death of one animal and is plotted on the day when this death occurred. The black lines, starting from the black dot, are extended to the right, and the crosses on these lines represent the death of a single animal on a certain day, and indicate the group to which the animal belonged.

First Group.—Line 1 (May 26) shows 4 deaths in two daily groups. At this date the barometric pressure was at its crest. Line 2 (May 29) reveals 4 deaths in three daily groups. Low temperature and high barometric pressure existed. Lines 3 and 4 (May 30 and 31) show 4 deaths in three daily groups for May 30, and 6 deaths in four groups for May 31. On these two days we had noticeable atmospheric disturbance indicated by great differences between the maximum and minimum temperatures. With line 5 (June 1) 9 deaths

*From the Department of Pathology, University of Illinois, College of Medicine, Chicago. This study was made possible through a grant from the Division of Venereal Diseases of the United States Public Health Service.

Received for publication, February 6, 1941.

were observed in five groups. The temperature was falling and barometric pressure was rising (polar air mass). On line 6 (June 2) 11 deaths in six daily groups are noted. Difference between maximum and minimum temperatures was well pronounced, and the mean temperature decreased slowly. Line 7 (June 3) indicated 14 deaths in seven daily groups. There was a fall in temperature and a sharp rise in barometric pressure (polar air mass).

Chart 1.—Mortality protocol of rats infected with neoarsphenamine. Spring and autumn groups. Upturned arrows indicate days of increased mortality.

Second Group.—In the September to October group line 8 (September 23) indicates 12 deaths in three daily groups. On this day there was a drop in temperature and the difference between maximum and minimum temperatures was pronounced. Lines 9 and 10 (September 25 and 26) reveal the passage of a major polar air mass. Twenty-seven deaths are indicated in six groups on September 25, and 13 deaths in four groups on September 26. Line 11 (September 28) reveals 12 deaths in three daily groups. The difference between maximum and minimum temperatures on this day was large. Line 12 (September 30) falls on the day of a polar front; 6 deaths were recorded in two daily groups. Lines 13 and 14 (October 1 and 2) indicate 8 deaths in four groups, and 9 deaths also in four groups. The barometric pressure was still rising, the temperature was comparatively low, and the difference between

maximum and minimum temperatures was pronounced. Lines 15 and 16 (October 3 and 4) show 6 deaths in three groups (October 3), and 12 deaths in four daily groups (October 6). On these days the temperature was rising and barometric pressure was falling. Disturbance is indicated by the large differences in maximum and minimum temperatures.

Chart 2.—Graph to illustrate similar trends in mortality for the autumn rat and rabbit groups.

From these observations the following conclusions may be drawn:

1. Neoarsphenamine is more toxic to white rats when meteorologic disturbances at the time of its administration are more pronounced.
2. The most toxic effects of neoarsphenamine in white rats are found to be on the days when the temperature is low and the barometric pressure is high (passing of polar air masses).
3. Neoarsphenamine is more toxic on the days when the temperature rises rapidly and the barometric pressure falls abruptly.
4. Neoarsphenamine is also somewhat more toxic when the difference between the maximum and minimum temperatures is great.
5. Increased toxicity holds for the deaths occurring immediately after the injection of neoarsphenamine as well as for delayed deaths.

Rabbits and Rats of September-October Group.—During the experimentation from September to October, 1939, it was possible to give the injections to rabbits (Nedzel) and white rats simultaneously. The results are presented in Chart 2. It becomes quite evident that the days when a larger number of deaths occurred among rabbits, a larger number of deaths among the rats also occurred (lines 1, 2, 3, 4, 5, and 6).

The following conclusions seem justified:

1. Similar environmental situations increase the toxicity of neoarsphenamine for different kinds of animals (in this case, rabbits and white rats).
2. Some days when rabbits survived or died in smaller numbers, were more fatal for the rats because of their greater susceptibility to the neoarsphenamine.
3. The days on which rats survived or died in a small number coincided with similar lessening of deaths for rabbits.

A RESPIRATION TAMBOUR WITH SOME UNIQUE FEATURES*

HANS ASH, GALVESTON, TEXAS

MANY varieties of respiration tambour are now in use in teaching and research laboratories. It is safe to say, however, that there is room for improvement in this type of apparatus. In teaching laboratories the simply constructed apparatus is preferred. Because it is handled by inexperienced hands, a breakdown of the apparatus occurs frequently in the middle of an experiment.

A respiration tambour should give satisfactory recordings from large animals, such as dogs, as well as small animals, such as rabbits. A correct recording from any kind of pneumograph or stethograph is advantageous. The cost of the apparatus should be reasonably cheap. The apparatus herein described meets these requirements. In addition it is easily adjusted. This eliminates confusion and may save the experiment.

This tambour is shown in Figs. 1, 2, and 3. The air cup *P* is cone-shaped, 42 mm. by 35 mm. This shape appears to eliminate some vibration of the writing lever. It produces a satisfactory record on the kymograph paper even with small animals, from which a good record is sometimes hard to obtain with many tambours.

An important adjustable feature is a flat piece, 35 mm. by 7 mm. by 4 mm.; *A*, Fig. 1, with one end fastened to the bottom of the tambour cup with an adjustable screw *B*. This enables arm *A* to be swung into any horizontal position. The opposite end of *A* is of different dimensions, 8 mm. by 7 mm. by 7 mm. Through a hole in this end, a vertical rod *C*, 80 mm. by 4 mm., is fitted.

*From the Department of Pharmacology, Medical School, University of Texas, Galveston.
Received for publication, February 10, 1941.

The bottom end of this rod is smaller in diameter than the top, the lower 30 mm. being 3 mm. in diameter instead of 4 mm., as it is at the top. This prevents the rod from slipping down in its entire length when being adjusted. A screw, *D*, in the end of the bottom piece, *A*, clamps the rod in the desired position. This rod adjusts the position of the writing lever in the horizontal plane. The top of the rod *C* is square; *E*, Fig. 2, measures 8 mm. by 7 mm. by 7 mm. Through a hole in this end is a horizontal rod *F* (Fig. 2), 70 mm. by 3 mm. One end of rod *F* is threaded and holds the lever assembly *G*. Movement of the lever assembly *G* about the axis of rod *C*, and by means of adjustment of the distance of this assembly from *E* accomplishes the change of position of the lever assembly to either side of the assembly *I*, which transmits the force from

Fig. 1.—Lever joint is placed in front of the connection pin, reversing the direction of the writing level from the usual arrangement.

the tambour to the writing lever, *J*. Rod *F* is clamped in position with screw *H* on the end of vertical rod *C*. This change in position of the lever assembly *G* with reference to the fulcrum assembly *I*, enables one to change the direction of the movement of the lever. And in this way an adjustment to any type of pneumograph or stethograph can be made to obtain an upward movement of the record to represent inspiration. So far as we know this is a unique feature of this apparatus.

The footplate *K*, which is cemented to the rubber diaphragm, is connected to *I* by means of a swivel joint. This arrangement prevents the tearing loose of the footplate from the diaphragm when adjustments of the writing lever are made. This feature is also unique and can be used on any kind of tambour.

The writing lever *J* consists of an ordinary aluminum or straw heart lever. It is attached at *L* to the permanent portion of the lever assembly. It is, however, attached to the pivot *M* of the lever assembly with a small screw *N* set in a block *O*, in the same manner as an open-jawed support clamp. By this means,

the lever may be moved not only backwards and forwards but it may also be lifted out of the block *O* from any position. The block *O* which holds the lever is also attached to pivot *M* by the same arrangement.

Fig. 2.—Writing lever turned in one of the many directions in which it can be placed.

Fig. 3.—The lever joint is placed behind connection pin as in the usual tambour arrangement.

The apparatus is made of sheet copper and brass rod which are nickel-plated. The cost is reasonable and the apparatus is easily made by any competent mechanic.

THE SEDIMENTATION RATE IN GOUT*

RUSSELL L. HADEN, M.D., AND JACK KINELL, M.D.
CLEVELAND, OHIO

THE sedimentation rate of erythrocytes has been investigated thoroughly in most rheumatic states, but it has not been studied to any extent in gout. Hill,¹ and Gibson and Kersley,² report the sedimentation rate in a fairly large series of cases of gout. A few other reports, representing small series of cases, have appeared. Here, however, the records relative to the sedimentation rate in gout have been presented only as interesting observations incidental to the study of joint disease as a whole.

PROCEDURE

We have studied the sedimentation rate in 100 consecutive cases of gout; 21 of these were patients with tophaceous gout and 79 were of the pretophaceous type. The diagnosis in the latter group was established by careful consideration of the history and physical and laboratory findings. The patients also were studied with reference to the activity of the disease at the time the examination was made. The level of uric acid in the blood was likewise determined.

For comparison, the sedimentation rate was measured in 50 apparently normal persons, in 100 consecutive cases of rheumatoid arthritis, and in 100 consecutive cases of osteoarthritis.

The erythrocyte sedimentation rate was determined by the method of Rourke and Ernstene³ in which correction is made for the red blood cell volume. The upper limit of normal is considered 0.45 mm. per minute. The blood uric acid determination was made by the Morris-Macleod⁴ technique and 2.5 mg. per cent was taken as the upper limit of normal.

RESULTS

The sedimentation rate in 100 cases of gout in all stages of activity ranged from 0.22 to 2.30 mm. per minute, with an average rate of 0.94 mm. per minute; 87 per cent of the patients showed an increase in the rate above the upper limit of normal of 0.45 mm. per minute (Table I).

The average sedimentation rate found in the normal group, in the group with osteo-arthritis, and in the rheumatoid group was 0.24, 0.51, and 0.98 mm. per minute, respectively. These are shown and compared with the gout group in Table II.

In Table III is recorded the average sedimentation rate found when the cases of gout were classified according to the activity of the disease. The average

Received for publication, February 12, 1941.

blood uric acid for each of these groups is noted also. The average rates found are 1.13, 0.87, 1.21, 1.02, and 0.68 mm. per minute for the acute, acute subsiding, chronic progressive, chronic, and inactive groups, respectively. The average blood uric acid values are 3.8, 3.7, 3.3, 3.9, and 4.0 mg. per cent for each group given in the same order.

TABLE I
SEDIMENTATION RATE IN GOUT

Sedimentation rate in millimeters per minute	Under 0.46	0.46-0.60	0.60-0.80	0.80-1.00	1.0 Plus
Number of cases	13	8	16	15	48
Per cent	13.0	8.0	16.0	15.0	48.0
Average sedimentation rate	0.94 mm. per minute				
Highest	2.30 mm. per minute				
Lowest	0.22 mm. per minute				

TABLE II
COMPARISON OF SEDIMENTATION RATES IN NORMAL PERSONS, ARTHRITIS, AND GOUT

DIAGNOSIS	NUMBER OF CASES	AVERAGE SEDIMENTATION RATE
Normal persons	50	0.24
Osteo-arthritis	100	0.51
Rheumatoid arthritis	100	0.98
Gout	100	0.94

ACTIVITY OF DISEASE, AVERAGE SEDIMENTATION RATE, AND AVERAGE BLOOD URIC ACID IN GOUT

	ACUTE	ACUTE SUBSIDING	CHRONIC PROGRESSIVE	CHRONIC	INACTIVE
Number of cases	45	26	2	9	18
Per cent	45.0	26.0	2.0	9.0	18.0
Average sedimentation rate in millimeters per minute	1.13	0.87	1.21	1.02	0.68
Average blood uric acid in milligrams per cent	3.8	3.7	3.3	3.9	4.0

DISCUSSION

Since the original investigations of Fahraeus⁵ on the sedimentation rate of erythrocytes, much interest has been shown in this property of the red blood cells. Many studies in rheumatic disorders have shown the sedimentation rate to be consistently elevated in rheumatoid arthritis, with only slight elevation in the osteo-arthritic type, probably not out of proportion to the advanced age of the persons in whom it occurs. The findings of others have been essentially in agreement with the average values cited in Table II, taken for comparison with our average values for gout.

In the occasional case of gout studied with reference to the sedimentation rate, there has usually been a tendency to an increased velocity of settling of the erythrocytes, but the striking uniformity in this increase in the rate and the magnitude of this increase probably has not been properly appreciated. Kahlmeter,⁶ in a discussion on the sedimentation rate in rheumatic disorders,

reported observations with respect to this in 6 cases of gout, 3 active and 3 chronic. He found the sedimentation rates definitely elevated in the active cases with rates only slightly above normal in the chronic cases. He does not indicate clearly whether the cases in the latter group represent chronically active disease or whether they are merely cases of long duration with intermittent clinical activity. Hench⁷ states that the sedimentation rate is elevated in gout but he does not further elaborate on this statement of fact. Hill,¹ reporting his observations on 93 cases, observed that the sedimentation rate varies considerably in gout, being markedly increased only during acute attacks and returning quickly to normal following the acute episode. Gibson and Kersley² found the erythrocyte sedimentation rate to be increased in 59 per cent of 68 cases of gout they studied. It is their belief that the sedimentation rate measures the factor of severity of the local tissue reaction.

Although the average rate found here for the 100 consecutive cases was 0.94 mm. per minute and an elevation above normal occurred in 87 per cent of the patients, it should be emphasized that the sedimentation rate may be found to be within normal limits in certain instances. Thirteen of the 100 patients had rates of 0.45 mm. per minute or less. However, in each instance the gout was either subsiding after an acute exacerbation or was classified as inactive. On the other hand, many cases of inactive and subsiding acute gout were seen in which the readings were decidedly elevated.

The sedimentation rate tends to reflect in part, at least, the activity of the disease. This interesting observation is drawn from examination of Table III, where it is seen that the highest average values in the common type of intermittently active gout occurs in the group representing the acute phase of the disease. As the process becomes less active, the average rate is reduced, as noted in the average values found in the acute subsiding and inactive groups. When the disease tends to be of a progressive nature, the sedimentation rate reaches its highest level. The observations made in this particular group, however, represent only 2 cases and are, therefore, subject to criticism. The average value found in the chronic group is about as would be expected, being neither extremely high nor as low as in the inactive group. The shift in the sedimentation rate noted with respect to the activity of the disease is, of course, not peculiar to gout. Essentially the same reaction is encountered in rheumatoid arthritis.

There is no adequate explanation for the elevation of the sedimentation rate in gout at the present time. Infection is certainly not a factor, for careful survey of these individuals for chronic foci has usually proved unsuccessful. Treatment or removal of infected teeth, tonsils, sinuses, or prostate glands had been carried out in 45 per cent of these cases before they came under our observation, without affecting the course of the disease. Gilligan and Ernstene⁸ have demonstrated that the plasma fibrinogen level is the major factor in controlling the sedimentation rate. Assuming an increase in the plasma fibrinogen in gout, one may offer a possible explanation on a basis of faulty intermediary protein metabolism or perhaps on the basis of impaired liver function. A functional disturbance in the liver in gout does not seem unlikely, since these patients

are almost uniformly obese and are notorious for their indiscretion regarding diet and the use of alcohol.

An examination of the data, as shown in Table III, fails to reveal any parallelism between the sedimentation rate and the level of the blood uric acid which reflects in part, at least, the extent of metabolic dysfunction.

SUMMARY

1. The sedimentation rate was found to be elevated above 0.45 mm. per minute in 87 per cent of 100 cases of gout. The average rate for the series was 0.94 mm. per minute. The upper limit of normal by our method is 0.45 mm. per minute.

2. For comparison the sedimentation rate in 50 apparently normal persons, 100 cases of osteo-arthritis, and 100 cases of rheumatoid arthritis was determined. The average rates found were 0.24, 0.58, and 0.98 mm. per minute, respectively.

3. The sedimentation rate varies with the activity of the disease, being lower in acute subsiding cases than in acute cases, and reaching its lowest level in inactive cases. It reaches its highest level in the chronic progressive type of gout and an intermediate level in the simple chronic type of the disease.

4. There is no apparent correlation between the sedimentation rate and the degree of metabolic dysfunction, as indicated by the level of the blood uric acid.

5. The sedimentation rate may at times be of value in the differential diagnosis of gout, osteo-arthritis, traumatic arthritis, bursitis, tendonitis, fibrositis, and peri-arthritis.

THE ROLE OF AUTO-ANTIBODIES IN THE SERODIAGNOSIS OF SYPHILIS*

A. W. RATCLIFFE, M.D., CHICAGO, ILL.

THE history of the serodiagnosis of syphilis and the speculation as to the nature of the constituent of serum that reacts with tissue lipids in the present-day serodiagnostic tests for syphilis have been summarized by Eagle.^{9, 10} From the 1937 summary⁹ it seems controversial as to whether reagin is an antibody to lipid haptens of the host, liberated at foci of infection and activated by spirochetal protein, or an antibody to the spirochete which contains a lipid related to those found in mammalian tissues (and in vegetables,³⁶ as well as possibly in other bacteria and protozoa, the so-called ubiquitous lipid). Recent work with the spirochetal complement-fixation test¹⁰ seems to indicate that the spirochete of syphilis stimulates the production of at least two *separate* antibodies, (a) antilipid and (b) antispirochetal, both in response to substances contained in the spirochete.

With no thought of disparaging this admirable work, but rather with the hope of emphasizing its potential significance, exception must be noted to the implication of the repeated statement that "there seems no a priori reason why spirochetal protein should uniquely activate the lipoidal tissue hapten and thus initiate antibody production, while in other conditions in which there is just as much tissue destruction and in which some other bacterial protein is available as the activator, the Wassermann remains consistently negative."^{9, 10} While there is indeed no apparent "a priori reason," the implication that serodiagnostic tests for syphilis remain consistently negative in other conditions is not beyond question.† From the reports of biologically positive reactions in certain nonsyphilitic diseases in man^{1, 6, 7, 9, 25, 26, 28, 32-34} and lower animals,²⁴ the occurrence of positive reactions in apparently normal lower animals^{9, 13, 31} and the possible occurrence of reagin in normal human serum² all constitute evidence that must not yet be disregarded.

Rosebury¹² pointed out that, theoretically, spirochetal protein is not necessary for the activation of autogenous lipoidal haptens, and Kahn¹⁸ emphasized the possibility that in the presence of tissue destruction lipid protein combinations may be liberated similar to those liberated in syphilis. He further pointed out that in rare instances traces of tissue proteins and lipids liberated in the process of metabolism might be sufficient to stimulate antibody production against lipids.

The production of auto-antigens within the living body of an experimental animal (guinea pig) by application of the physical agents of heat or cold has recently been reported by Karady¹⁹ but has not been confirmed.

Reference has already been made to the occurrence of positive reactions in man in certain diseases other than syphilis. Particular attention is called to the report of Taoka³³ that positive serologic reactions were found in 24 per cent of 100 patients with carcinoma of the cervix uteri as compared with only 10.38 per cent of 106 general in-patients; also Stojalowski³² found that of 830 cases studied by post-mortem examination there were 15 with no post-mortem sign of syphilis, which had been diagnosed and treated for syphilis. In 3 cases serologic tests were not done; in 3 cases serologic reactions were negative; and, in 7 cases serologic tests were done only in the moribund stage. In correlating the post-

*From the Department of Pathology, Northwestern University Medical School, Chicago.
Received for publication, February 20, 1911.

†Since this was written the following papers have been published:

Kahn, R. L.: A Serologic Verification Test in the Diagnosis of Latent Syphilis, *Arch. Dermat. & Syph.* 41: 817, 1910.

Moore, J. E., Eagle, H., and Mohr, C. T.: Biologic False Positive Serologic Tests for Syphilis, *J. A. M. A.* 115: 1602, 1910.

mortem histologic diagnoses with the serologic findings he found that: of 2 cases of carcinoma 2 were positive; of 5 cases of tuberculosis 2 were positive; and of 5 cases of myocarditis 2 were positive.

It has been reported that positive serologic reactions for syphilis have been induced in rabbits by the injection of various preparations. These include: killed cultures of *T. pallidum*;^{20, 21} aqueous extract of syphilitic liver;^{5, 11, 16} alcoholic extract of syphilitic liver¹¹ and syphilitic rabbit's testicle;¹⁴ mixtures of lipid extracts from various normal human, rabbit, or beef organs with some foreign protein;^{4, 8, 15, 16, 30, 35} a mixture of lecithin and hog serum;²⁷ washed floccules from positive reactions of human serum from syphilitic patients^{3, 8, 29} and from malarial patients,²⁹ and of pooled bovine serum,²⁹ and syphilitic rabbit serum;³ aolan;²⁷ and emulsions of hamster tissues.²⁸ Positive reactions in rabbits have also been noted as a result of experimental infection with bovine tubercle bacillus,²⁴ and have been induced in human beings by the injection of killed cultures of *T. pallidum*,²² and killed trypanosomes.^{23, 38}

Reports of unsuccessful attempts to produce artificial positive reactions in rabbits include the injection of alcoholic extracts of normal human heart and normal infant liver;¹¹ alcoholic extracts of (syphilitic ?) liver;¹⁶ alcoholic extracts of normal rabbit's testicle;¹⁴ turpentine, dilute alcohol, and *b*-tetrahydronaphthylamine;²⁴ and floccules from positive tests on normal rabbit serum,⁸ and human leprous serum (one trial only).²⁹

Because of the incidence of positive reactions in rabbits,^{9, 13, 24, 31} it is difficult to interpret all of these reports. However, they seem to indicate that it is possible artificially to induce positive serologic reactions in rabbits by various methods, many of which in no way involve either *T. pallidum* or any specific derivative of it.

With these things in mind it appeared that the auto-antibody theory might account for positive reactions with lipid antigen in the absence of syphilis, and that it might be susceptible to investigation by animal experimentation.

EXPERIMENTAL

Materials and Methods.—Rabbits, after preliminary serologic study, were variously treated in attempts (a) to produce pathologic changes characterized by chronic inflammation and degenerative changes simulating the essential lesions of syphilis while observations of the reagin titer were made at frequent intervals; or (b) to stimulate or to augment the production of reagin by the injection of various extracts of homologous tissue or preparations of autogenous serum.

Necropsy has been performed upon these animals to observe any correlation between the serologic findings and the pathologic changes.

The serologic examination included the Kahn Standard, Kline Diagnostic, and the Mazzini flocculation tests; quantitative tests were done whenever a four-plus reaction was encountered. Complement-fixation tests were attempted, but the high incidence of anticomplementary reactions rendered the results almost worthless. For a time the sera were heated for thirty minutes at 62° C. instead of 56° C., in an attempt to reduce the incidence of these anticomplementary reactions. It was observed that heating at this higher temperature reduced not only the anticomplementary activity but also the reagin titer; consequently, this deviation from the regular technique was soon abandoned.

Incidence of Serologic Reactions in Untreated Rabbits.—The sera from 18 rabbits were tested after heating at 56° C. for thirty minutes; 2 were Kahn negative, 2 were Kline negative, and 6 were Mazzini negative. The reactions of the others ranged from a one-plus reaction to a titer of 5. Three rabbits were not tested with the complement-fixation test and 2 of them were anticomplementary in all reacting dilutions; of the 13 on which readings were obtained, 7 were negative.

The sera of 10 rabbits were tested after heating at 62° C. for thirty minutes; 10 were complement-fixation-negative, 8 were Kahn negative, 8 were Kline negative, and 8 were Mazzini negative. The same 2 rabbits reacted in the Kline and Mazzini tests; the 2 rabbits which reacted in the Kahn test were negative to all other tests.

From these groups animals were chosen for further study.

Variation of Serologic Titer in Untreated Rabbits.—Of the 8 rabbits first chosen for study all but one showed considerable variation of reagin titer, as demonstrated by the flocculation tests; one animal gave consistently negative results with all tests. A study of the records of these animals reveals that (a) upon repeated examination the various techniques did not show similar variation of titer, one rabbit excepted; (b) upon repeated examination with a given technique the various animals did not show a uniform variation from the titer of the previous examination with the same technique; and (c) in general, the Mazzini technique in repeated examinations of a given animal seemed to show a lower titer and less variation in titer than did either the Kline or Kahn test; one rabbit represents an exception to this observation and exhibited a lesion (echinococcal cyst) not found in the other animals.

While the possibility of some daily variation in the sensitivity of the various antigen emulsions cannot be completely ruled out, these observations are considered as sufficient evidence for the belief that this factor does not account for the variations in titer observed under treatment.

PATHOGENIC AND IMMUNOLOGIC PROCEDURES

1. *The injection of flocculate from positive human serum.* In order to secure a preliminary observation as a basis of comparison, a female rabbit, which had shown clearly negative results over a period of six weeks, was given weekly intravenous injections of washed flocculate from mixtures of Mazzini-antigen suspension and positive human serum. A total of 9 injections of floccules from 0.6 ml. of four-plus serum was given.

One week following the third injection the Kahn test showed a one-plus titer; the following week this had increased to a two-plus. Just before the fifth injection the Kline, Mazzini, and complement-fixation tests showed partial positives for the first time. The Mazzini test gradually rose to a titer of 10 before the eighth injection. During the following week it dropped sharply to one-plus.

2. *Intra-abdominal transplant of rabbit's aorta.* A freshly removed rabbit aorta was placed in the peritoneal cavity of a female rabbit. No abnormalities were observed, and clinical recovery was uneventful. The Kahn titer rose from

one-plus to two-plus two weeks after the operation, and was maintained at this level until the seventh week when it dropped again to one-plus. The Kline titer was slightly diminished during the first four weeks, returned to one-plus in the fifth week, rose slightly in the sixth week, and returned to one-plus in the seventh week. The Mazzini titer was slightly elevated in the fourth, fifth, and sixth weeks, and again dropped to negative in the seventh week. Necropsy in the eighth week showed an encysted granulomatous mass enclosing the transplanted aorta.

3. *Ligation of the splenic pedicle.* A female rabbit was subjected to laparotomy, at which time the splenic pedicle was ligated. No abnormalities were observed, and clinical recovery was uneventful.

The Kahn titer rose to three-plus in ten days and to four-plus in thirty-one days after the ligation. During the next week it dropped to one-plus. The Kline and Mazzini tests showed no significant variation of titer. The complement-fixation test was one-plus two and one-half weeks after surgery, but later examinations were again negative. Necropsy in the seventh week revealed replacement of the greater portion of the spleen by a nonspecific granulomatous mass exhibiting central necrosis resembling caseation.

4. *Injection of homologous tissue preparations.* The heart, aorta, liver, brain, and psoas major muscles of an untreated female rabbit were dehydrated in repeated changes of acetone. The dehydrated tissue was finely chopped and mixed for the preparation of the various extracts.

A. *Aqueous extract of homologous tissues*

Three grams of this dehydrated rabbit tissue were mixed with 50 ml. of 0.85 per cent sodium chloride solution and shaken mechanically for an hour. This mixture was filtered, the residue was discarded, and merthiolate, 1:40,000, was added. Two rabbits were given weekly intra-abdominal injections of this aqueous extract, starting with a dose of 1 ml. and increasing to 3 ml. in the seventh week. One rabbit showed no significant variation in serologic titer during eight weeks, nor were significant changes found at necropsy. The other rabbit showed some fluctuation in the Mazzini titer, and a gradual increase in the Kahn titer from negative at the end of the second week to three-plus at the end of the eighth week. This latter rabbit at necropsy exhibited a splenic lesion which consisted of a cystlike yellow mass containing dirty dark-brown cheesy material. Microscopically, it could be seen that the yellow color was due to yellow droplets in phagocytic cells which composed the inner portion of the "cyst" wall. These cells appeared to be large mononuclear cells, which in some areas exhibited a loss of cell outline and resembled syncytium. Multinuclear cells of the foreign-body type were seen. The etiology of this lesion remains obscure.

B. *Lipid extract of homologous tissues*

Fifteen grams of the dehydrated rabbit tissues were treated to obtain ether-soluble acetone-insoluble and ether-insoluble alcohol-soluble fractions which were mixed in alcoholic solution and portions used for injection after being quickly added to an excess of 0.85 per cent sodium chloride solution.

Two rabbits got weekly intra-abdominal injections of this extract, 0.5 ml. in each of the first four doses and 1.0 ml. in each of the last three. One of these rabbits after negative preliminary tests exhibited a gradual rise to a two-plus Kahn and a one-plus Kline and Mazzini; no significant lesions were found at necropsy. The other rabbit exhibited preliminary reactions varying between three-plus and a titer of 10. Under treatment the Mazzini titer was constant at four-plus; the Kline fluctuated from a level of three-plus; and the Kahn was at first diminished to a two-plus and then rose to a four-plus level. At necropsy an echinococcal cyst was found.

C. *Protein derivatives of rabbit tissues (peptic metaprotein)*

The residue of the rabbit tissues after ether and alcohol extraction as already described was treated with 150 ml. of 0.3 per cent hydrochloric acid and approximately 0.25 Gm. of pepsin. After ten minutes at 37° C. a small portion was separated, while the remainder was permitted to stand for four hours at this temperature. The material was filtered, neutralized with sodium hydroxide, and heated to boiling. The products of the ten-minute and the four-hour incubations were mixed. This preparation yielded positive biuret and xanthoprotein reactions; Millon's reaction was negative. A precipitate formed upon the addition of ammonium sulfate, but boiling did not cause precipitation. Merthiolate, 1:40,000, was added.

Two rabbits were treated with weekly intra-abdominal injections of this preparation, the doses increasing from 1.0 to 3.0 ml. in the ninth week. Both animals showed slight increases of the Kahn titer without significant change in the results of the other tests. Neither animal showed significant lesions at necropsy.

D. *Recombined lipid and peptic metaprotein from rabbit tissues*

A portion of the peptic metaprotein extract was treated by adding to it, drop by drop, during vigorous agitation, the lipid extract (B) until a preparation resembling clear yellow blood serum was obtained.

Six rabbits were treated with weekly injections of this preparation in doses increasing from 1.0 to 3.0 ml. in the ninth week. Two showed very slight transient increases of titer. Necropsy revealed in one cysticercoid cysts of the omentum and in the other a 5 mm. encysted granulomatous abscess located retroperitoneally. One showed fluctuation of the previously constant Kahn titer in an elevated range; necropsy revealed no significant lesions. Two showed primary diminution and secondary elevation of titer, most marked in the Kahn, but also evident in the other flocculation tests; necropsy revealed no significant lesions in one of these, while in the other occasional small areas of patchy necrosis were present in the renal cortex. One, after a previously negative reaction, showed a definite rise of titer, evident in all the tests and comparable to that seen in the rabbit injected with flocculate from human syphilitic serum. Aside from blindness, probably of glaucomatous origin, this rabbit exhibited no significant lesions.

5. *Injection of heated autogenous serum.* Two rabbits were treated with autogenous serum which had been heated one hour at 56° C. The dosage was

0.5, 0.75, 1.0, 1.0, 1.0, and 1.0 ml. at weekly intervals. In one rabbit these doses were reinforced with 0.2 ml. of a 5 per cent suspension of collodion particles prepared by the method of Zozaya.³⁷ Both animals showed a gradually increasing Kahn titer during the first four weeks, after which the titer dropped in each case. The Kline and Mazzini titer gradually decreased during the period of treatment. Neither rabbit exhibited significant pathologic changes at necropsy.

DISCUSSION

The production of a positive serologic reaction following the injection of flocculate from human syphilitic serum has been frequently reported and was readily confirmed. The fall of titer that occurred during the eighth week while the injections were still in progress does not seem to have been previously reported. Neither has the apparent partial specificity of the antibody produced for the particular antigen flocculate been emphasized.

The pathogenic procedures of aortic transplantation and splenic ligation were each successful in producing local lesions of the desired type. A somewhat similar lesion occurred, apparently spontaneously, in one of the rabbits treated with aqueous extract of rabbit tissues and may account for the changes in titer observed in this animal.

It is probably apparent that among the various extracts of rabbit tissues the lipid-metaprotein preparation constituted the real test antigen, while the other preparations were employed as controls. In connection with the apparent slight antigenic action of the lipid extract it should be mentioned that its freedom from proteins is probably questionable. The colloidal state in which the lipid was injected might possibly tend to increase its antigenicity.

While with the exception of one rabbit treated with lipid-metaprotein preparation these changes are not of convincing magnitude, they are all compatible with the auto-antibody theory and are best explained by it. Furthermore, the changes in human subjects where the auto-antibody mechanism may be the responsible factor are usually of similarly slight degree.

The significance of the spirochetal complement-fixation test, especially when done after preliminary absorption with lipids, becomes even greater in the face of such an auto-antibody theory.

SUMMARY

Attempting to demonstrate evidence which would support or controvert the auto-antibody theory in accounting for nonspecific reactions with lipid antigens in serodiagnostic tests for syphilis, rabbits were subjected to various treatment intended to stimulate or to augment the production of reagin by non-specific and noninfectious means.

1. Granulomatous lesions were produced in 2 rabbits by surgical procedures; both animals exhibited slight elevations of Kahn titer between the second and seventh weeks.
